(Received 1st March 1965)

Summary. Unilateral cryptorchidism has been produced in prepubertal rats by abdominal fixation of an undescended testis and in adult rats by transplantation of a previously descended testis from the scrotal sac into the abdominal cavity. The incorporation of L-lysine-U-14C into protein of slices of both types of experimentally induced cryptorchid testes 30 days following the surgical procedure has been found to be markedly greater than that observed for slices of contralateral, scrotal testes of the same animal.

It has long been known that cryptorchidism leads to severe spermatogenic damage. In addition, the undescended testis has been reported to be over thirty times more likely to become malignant as compared to a normal, scrotal testis (Campbell, 1942). For these reasons, our laboratory has initiated studies on the metabolism of mammalian testicular tissue beginning with an investigation of the incorporation of 14C-labelled lysine into rat testicular protein. It was initially found that the incorporation of L-lysine-U-14C into protein of slices of cryptorchid testes which were experimentally-induced in adult rats was much greater than that observed for slices of scrotal testes obtained from the same animal (Davis, Morris & Hollinger, 1964). The present experiments were designed to explore further this finding, as well as to investigate the physiological significance of inducing cryptorchidism by transplanting a previously descended adult testis from the scrotal sac into the abdominal cavity.

Unilateral cryptorchidism was experimentally produced in two groups of male Sprague-Dawley rats. The first group (five animals) consisted of prepubertal rats which were 20 days of age and in which the testes had not yet begun their descent. Abdominal fixation of the undescended testis was carried out by performing a midline abdominal incision under ether anaesthesia and suturing the right testis to the dorsolateral abdominal wall, thereby preventing its normal descent. A fine 6-O surgical silk suture was passed just under the

tunica albuginea. Care was taken to avoid any interruption of the testicular artery by placing the suture beyond the point where the testicular artery enters the parenchyma of the testis. No evidence of testicular ischaemia was observed up to 30 days following the surgical treatment, which was the time period studied in the present investigations. Closure of the inguinal canal was not performed inasmuch as it was found that suturing alone was capable of preventing testicular descent. The left testis of the same animal was not sutured and was observed to descend into the scrotal sac when the animal reached approximately 35 days of age. Following abdominal fixation of the prepubertal testis, only a slight increase in weight was observed for the undescended, cryptorchid right testis, which reached a maximum weight of approximately 300 to 400 mg at the 20th day after surgery. The left testis, on the other hand, showed a marked and continual increase in weight until the 30th day after the surgical procedure when it began to level off at approximately 1500 mg.

The second group (five animals) consisted of adult rats which were 60 days of age and whose testes had undergone a normal descent into the scrotal sac. Transplantation of the adult testis from the scrotal sac into the abdominal cavity was performed by making a midline abdominal incision and applying gentle pressure to the bottom of the scrotal sac. The right testis was then sutured to the dorsolateral abdominal wall in a similar manner to that previously described. The left testis of the same animal was allowed to remain in the scrotal sac to serve as a control. Following abdominal transplantation of the previously descended adult testis, a progressive decrease in the weight of the

cryptorchid right testis occurred from approximately 1500 mg to a weight of 300 to 400 mg at the 20th day post-operatively. The left scrotal testis of the same animal did not change in weight to any significant extent during this period. These data indicate that the difference in weight of the scrotal and the cryptorchid testis appears to be quite similar in both types of experimentally-induced cryptorchidism.

At various time periods ranging from 5 to 30 days after the surgical procedure, the animals of both groups were killed and both scrotal and abdominal testes removed. Following excision of the capsule, slices of testes were obtained at 4°C with the aid of a Stadie-Riggs microtome. Incubation of the tissue slices was carried out in a Warburg apparatus as previously described (Davis, Firlit & Hollinger, 1963). The main chamber of the flask contained 150 to 200 mg wet weight of tissue in 3-0 ml of Krebs-Ringer bicarbonate buffer at pH 7-4. The side-arm contained 2.5 x 10⁶ counts/min of L-lysine-U-¹⁴C in a volume of 0-2 ml. The final concentration of radioactive lysine in the incubation flask was 1.8 x 10⁻⁵ M. The gas phase was 95 % O₂ and 5 % CO₂. At the end of a 1 hr incubation period at 37-5°C, the reaction was terminated by the addition of 0-3 ml of 5 n perchloric acid. The proteins were isolated, plated and assayed for radioactivity, employing a correction for self-absorption.

Text-fig. 1 presents a comparison of the incorporation of L-lysine-U-¹⁴C into protein of slices of cryptorchid rat testes which have been induced by both abdominal fixation of prepubertal testes and by abdominal transplantation of adult testes. The incorporation of labelled lysine into protein of the normal, scrotal testis was found to decrease markedly from a specific activity (counts/min/mg dry weight of protein) of over 6000 at 20 days of age to approximately 350 counts/min/mg at 60 days of age, where it remained constant throughout the remaining experimental period of the present studies. Protein labelling of the cryptorchid testis induced by the abdominal fixation of a prepubertal testis was also observed to decrease up to 15 days following its retention in the abdominal cavity; however, no further decrease in protein labelling occurred beyond this time so that, at 30 days after the surgical procedure, the specific activity of the protein of the cryptorchid testis was almost five times as great as the specific activity of the protein of the contralateral, scrotal testis. Following abdominal transplantation of a 60-day-old adult, scrotal testis, the uptake of L-lysine-U-¹⁴C into protein of the cryptorchid testis was found to increase markedly, reaching a maximum at the 20th day after the surgical procedure while protein labelling of the contralateral, scrotal testis remained constant.

These data indicate that the marked increase in protein labelling from L-lysine-U-¹⁴C which has been observed in cryptorchid rat testes induced by transplanting an adult, scrotal testis into the abdominal cavity has been found to occur also in cryptorchid rat testes which have been induced by the more physiological condition of preventing normal testicular descent by fixation of the abdominal testis prior to the onset of puberty. The possibility exists that the increase in testicular protein labelling found to occur in cryptorchidism may be due to an increase rate of protein biosynthesis occurring in the remaining cell types of the abdominal testis. Experiments are now in progress in this laboratory which are designed to compare further both types of experimentally-induced
cryptorchidism in terms of their histological appearance and radioautographic incorporation of tritiated lysine into protein of individual testicular cell types.
