The effects of charcoal-extracted bovine follicular fluid (BFF) on endocrine profiles and follicular development in intact and hemiovariectomized postpubertal heifers were examined. Oestrus-synchronized heifers received Norgestomet implants on day 1 and 7 of treatment and were then injected s.c. with 11 ml saline (control) or 11 ml BFF twice a day for 12 days. The ovary bearing the largest follicle (OV₁) was removed on day 7 and the remaining ovary (OV₂) was collected on day 13. Follicles were observed by daily ultrasonography and were classified according to diameter (size 1: 2–3 mm; size 2: 4–6 mm; size 3: 7–10 mm; size 4: > 10 mm). After ovarioectomy they were classified by diameter and histologically as normal or atretic. Intact control heifers had increased numbers of size 4 follicles on OV₁ on days 6 and 7; no increase was observed in BFF-treated heifers (P < 0.03). In BFF-treated heifers, the mean basal LH concentration was higher (P < 0.05) and that of FSH was lower (P < 0.04) than in controls. FSH concentrations in BFF-treated heifers decreased from 0.60 ± 0.08 ng ml⁻¹ (day 1) to 0.22 ± 0.05 ng ml⁻¹ (day 7; P < 0.04). The concentration of oestradiol increased in control heifers, but not in BFF-treated heifers (P < 0.001). After hemicastration, OV₂ underwent compensatory hypertrophy in control heifers, with an increase in the number of size 2, 3 and 4 follicles (P < 0.05), whereas BFF-treated heifers did not. Thus, total follicular volume was much lower in BFF-treated than in control heifers on day 13 (92.2 ± 15.4 versus 1393.8 ± 276.6 mm³; P < 0.0002). A transient increase in FSH (P < 0.006) and oestradiol (P < 0.01) concentrations occurred after hemiovariectomy in control but not in BFF-treated animals. In control heifers, an analysis of temporal relationships showed negative correlations between the volume of size 3 and size 4 follicles, and between FSH concentrations and the volume of size 3 and 4 follicles. A positive correlation was found between the mean diameter of the largest follicle and the concentration of oestradiol, whereas negative relationships were found between the concentrations of FSH and oestradiol, and between FSH and the mean diameter of the largest follicle. Analysis of the histological data showed that the number and volume of follicles > 8.57 mm was lower in the BFF-treated OV₁ ovary, whereas no differences were found for follicles ≤ 8.57 mm. An absence of or a lower number and volume of follicles ≥ 3.68 mm was observed in BFF-treated OV₂ compared with controls. We showed that: (i) compensatory hypertrophy in the remaining ovary occurs in heifers when the ovary bearing the largest follicle is removed; (ii) treatment with BFF decreases the FSH concentration and follicular development in intact postpubertal heifers, and prevents compensatory FSH increase and follicular growth after unilateral ovarioectomy; and (iii) the histological population of follicles < 3.68 mm in diameter are not altered following 12 days of BFF treatment. Our results suggest that follicular development beyond 3–4 mm in cattle depends on an adequate circulating concentration of FSH.

Introduction

Development of antral follicles during the oestrous cycle in cattle is characterized by two or three successive periods of
follicular development. Each consists of a phase during which follicles are recruited, followed by a phase of follicular selection that results in one selected follicle continuing its development into a dominance phase. The dominance phase is characterized by the growth of one large follicle (> 10 mm) per pair of ovaries (Webb et al., 1992; Fortune, 1994). However, more information on the physiological mechanisms leading to follicular recruitment, selection and dominance is required to understand the control of follicular kinetics in cattle.

Injection of charcoal-extracted bovine follicular fluid (BFF) selectively reduces circulating FSH concentrations in intact (Miller et al., 1979; Lussier and Carruthers, 1989; Moser et al., 1989; Zollers et al., 1989; Turzillo and Fortune, 1990, 1993; Adams et al., 1992; Wood et al., 1993), hemiovariectomized (Johnson et al., 1985; Moser et al., 1989) and ovariectomized cattle (Ireland et al., 1983; Beard et al., 1989, 1990), and the spontaneous release of FSH by bovine pituitary cells in culture (Lussier et al., 1993). The decrease in FSH concentration caused by the injection of follicular fluid was attributed to the action of inhibit in the anterior pituitary (Knight, 1991; Dalkin et al., 1993). Miller et al. (1979) and Quirk and Fortune (1986) observed delayed oestrus following luteolysis induced by PGF₂α when BFF was injected; the delay was related to the volume and duration of the BFF injections. We observed that the superovulatory response is altered following pretreatment with BFF for 6 days in cyclic heifers (Lussier and Carruthers, 1989). These studies suggest that BFF alters follicular development, although follicular development was not monitored during or following the BFF treatments.

Injection of BFF suppresses the postovulatory increase in the FSH concentration, delays normal follicular development following oestrus (Turzillo and Fortune, 1990) and prevents the growth of a dominant follicle (Kastelic et al., 1990; Adams et al., 1992; Turzillo and Fortune, 1993). Ovarian compensatory hypertrophy following unilateral ovariectomy has been reported in cyclic and postpartum cows (Hafez et al., 1964; Saiduddin et al., 1970; England et al., 1973; Merz et al., 1977; Grass and Hauser, 1981; Staigmiller and England, 1982) and in prepubertal heifers (Johnson et al., 1985; Moser et al., 1989). In some of these studies, hormonal responses were only partially evaluated and follicular development was not monitored during the compensatory response. There is no information about the effects of BFF on follicles < 4-5 mm, probably owing to the limited resolution of ultrasonography. The present experiment was therefore designed to investigate the effects of charcoal-extracted BFF on circulating hormone concentrations and on follicular development, as monitored by ultrasonography, macroscopic observations of ovarian structures, and histology of antral follicle populations in intact and hemiovariectomized postpubertal beef heifers.

Materials and Methods

Animals and treatments

Twelve crossbred beef heifers with a mean (± SEM) body mass of 384.6 ± 6.7 kg were randomly assigned to two treatment groups and held in the same pen. The heifers were synchronized for oestrus with two injections of cloprostenol (500 µg, i.m.; Estrumate: Cooper’s Agropharm, Ajax, Ontario) 11 days apart. On the morning of the second cloprostenol injection (day 1), heifers received a Nordestemet ear implant (Syncro-Mate-B: CEVA, Kansas City, KS) to prevent ovulation. The heifers were either injected with 11 ml saline s.c. (the control group) or 11 ml charcoal-extracted BFF s.c. (the BFF-treated group) at 12 h intervals. The 11 ml dose of BFF was chosen since it had previously been found that injections of 7 or 14 ml given s.c. for 6 days decreases circulating FSH concentrations; Lussier and Carruthers, 1989). The treatments began on day 1 and continued for 12 days.

On the morning of day 7, the first Nordestemet implant was replaced with a new implant and the ovary bearing the largest follicle (OV₁), as determined by daily ultrasonography (from day 1), was removed. The use of a Nordestemet implant prevented the possibility of removing ovaries bearing or not bearing corpora lutea on day 7 or 13. On the morning of day 13, the remaining ovary (OV₂) was collected. The treatment with BFF for 6 days before removing each ovary was intended to allow time for effects on the small and medium-sized antral follicles to be manifested, since development and maturation of these follicles requires approximately 6.9 days, as estimated by Lussier et al. (1987). Follicular fluid used for treatments was collected and processed as described by Lussier and Carruthers (1989). The charcoal treatment removed > 97.5% of the steroids in BFF; the final concentrations were: 2.7 ng progesterone ml⁻¹, 0.5 ng oestradiol ml⁻¹ and 1.7 ng testosterone ml⁻¹.

Ovariectomies were performed by right flank laparotomy under local anaesthesia in standing heifers. Heifers were tranquillized with an injection of 10 mg acepromazine maleate i.m. (Atravet: Ayerst Laboratories, Montreal) 30 min before surgery, and the surgical site disinfected. Lidocaine HCl (with 2% adrenaline; MTC Pharmaceutical Ltd, Cambridge, Canada) was infused to desensitize the surgical site (Short, 1987), and the ovaries were obtained using an ovariote. The animals were injected with 15 000 µl penicillin kg⁻¹ i.m. (MTC Pharmaceutical Ltd) beginning 12 h before the surgery and at 12 h intervals for 3 days.

Endocrine analysis

Endocrine profiles were assessed by taking heparinized and nonheparinized jugular blood samples at intervals of 12 h (08:00 h and 20:00 h) before BFF treatment. The nonheparinized samples were allowed to clot at room temperature (22°C) for 4–6 h. The heparinized samples were cooled immediately to 4°C and centrifuged (2000 g, 15 min, 4°C) within 2 h. Serum and plasma were then frozen at −20°C until assayed. Endogenous gonadotrophin concentrations were determined by double antibody radioimmunoassays in serum as described by Lussier and Carruthers (1989), except that the tracers were iodinated by lodogen (Pierce Chemicals, Rockford, IL). Briefly, FSH or LH (2.5–5 µg) was diluted with 20–35 µl of 0.5 mol phosphate buffer 1⁻¹ (pH 7.4), transferred to a capped vial containing 1 µg lodogen, and allowed to react for 6–7 min with 500 µCi ¹²⁵I (Amersham, Oakville). Labelled hormones were separated from free ¹²⁵I salt by chromatography on to a G-25 Sephadex column (PD-10; Pharmacia, Montreal). The
specific activity of the tracers was estimated at 45–55 μCi μg⁻¹.

Serum FSH concentrations were determined in a single assay as described by Lussier and Carruthers (1989). Briefly, we used ovine FSH (NIAMDD-oFSH-I-1) as the tracer, ovine FSH (NIAMDD-oFSH-RP-1) as the standard, rabbit anti-ovine FSH (NIAMDD-anti-oFSH-1) as the first antibody, and sheep anti-rabbit γ-globulin (J. G. Manns, University of Saskatchewan, Saskatoon) as the precipitating second antibody. The sensitivity of the assay was 0.06 ng per tube (0.30 ng ml⁻¹) and the intra-assay coefficient of variation was 5.1%.

Serum LH concentrations were determined in a single assay as described by Lussier and Carruthers (1989). Briefly, the assay used bovine LH (LER-1716-2; L. E. Reichert, Union University, Albany, NY) as the tracer, NIH-bLH-B10 as the standard, and rabbit anti-ovine LH as the first antibody (GDN no. 15; Dr G. D. Niswender, Colorado State University, Fort Collins, CO). The sensitivity of the assay was 0.025 ng per tube (0.125 ng ml⁻¹) and the intra-assay coefficient of variation was 10.8%.

For steroid analysis, follicular fluid and plasma (200 μl) were extracted with 3 ml hexane (BDH Chemicals, Montreal, Quebec), with 80.9% recovery, and the concentration of progesterone was determined in a single [¹²⁵I]progesterone-based assay as described by Rawlings et al. (1984). The sensitivity of this double antibody assay was 25 pg per tube (0.125 ng ml⁻¹) and the intra-assay coefficient of variation was 7.8%. Serum oestradiol (500 μl) and follicular fluid were determined in a single tritium-based assay as described by Rowell and Flood (1988) after extraction with 4 ml ethyl ether (Caledon Labs, Georgetown, Ontario), with 85% recovery. The sensitivity of the assay was 1 pg per tube (2 pg ml⁻¹) and the intra-assay coefficient of variation was 10.9%. Testosterone from follicular fluid was extracted using diethyl ether and the concentration was determined with a tritium-based assay as described by Cook et al. (1982), with a sensitivity of 5 pg per tube.

**Ovarian analysis**

Each morning of the experiment (day 1–day 13), except on day 12 because of technical difficulties, ovaries were scanned by linear-array ultrasonography (LS-300A; Tokyo Keiki Co. Ltd, Tokyo) using a 7.5 MHz transducer probe. The ovaries were localized by rectal palpation and scanned in a medial to lateral direction so that the follicles present could be observed (Guilbault et al., 1991). Each follicle was measured directly on the video screen using a caliper. The mean diameter was calculated with two perpendicular measurements and the approximate volume was calculated. Follicles were classified according to their diameter: size 1, 2–3 mm; size 2, 4–6 mm; size 3, 7–10 mm and size 4, > 10 mm.

After ovariectomy, the diameter of each visible follicle was measured macroscopically with a calliper applied directly on the ovarian surface; the volume was calculated and the size categorized according to diameter as described for ovarian ultrasonography data. The ovaries were embedded in paraffin wax, serially sectioned at a thickness of 7 μm, and every tenth section was mounted and stained in haematoxylin. All antral follicles > 0.13 mm were classified according to their largest diameter: class 2, 0.13–0.28 mm; class 3, 0.29–0.67 mm; class 4, 0.68–1.52 mm; class 5, 1.53–3.67 mm; class 6, 3.68–8.57 mm; class 7, > 8.57 mm (Lussier et al., 1987).

Each follicle was classified as normal or atretic according to criteria similar to those used by Grimes et al. (1987). Nonatretic follicles had well attached granulosa cells, with a regular internal border and an antrum with no cellular debris. The basal membrane was present, basal granulosa cells were cylindrical and pyknotic cells were either absent or scarce (<1%). In follicles with first degree atresia, granulosa cells were loosely attached and the internal border was irregular, pyknotic cells were present (1–8%), and cellular debris was often present in the antrum; the basement membrane and cylindrical basal granulosa cell layer were poorly defined and the theca interna was often thickened. In second degree atresia, 50% or more of the granulosa cells were lost, pyknotic cells were abundant and the theca interna was 2–3 times thicker than normal. Third degree atresia was characterized by an almost complete absence of granulosa cells (only 1–2 layers of cells with reduced area; i.e. nucleus and cytoplasm) and the presence of several pyknotic cells.

**Statistical analyses**

Ovarian follicular ultrasonography data and endocrine data were compared by analysis of variance (ANOVA) on raw data using a split-plot design with repeated measures in time. The general linear model (GLM) procedure of SAS (SAS, 1985) was performed with treatments as the main effect from day 1 to day 7 (before hemiovariecetomy) and from day 7 to day 13 (following removal of OV₁). Comparisons between treatment groups for each day were done by orthogonal polynomial contrasts, with degrees of freedom adjusted by the Greenhouse–Geisser Epsilon correction factor (Allen et al., 1983; SAS, 1985). The temporal relationship between FSH and oestradiol concentrations and follicular numbers or volumes per size within control heifers from day 1 to day 13, were performed by partial correlation analysis.

Macroscopic observations were compared by one-way ANOVA for numbers of follicles or volumes per follicular size, with treatment or ovaritectomy as main effects, comparing OV₁ or OV₂, and within control or BFF-treated heifers comparing OV₁ and OV₂. Histological observations were compared by one-way ANOVA with respect to the absolute number or relative number of follicles, and absolute follicular volume for each class, with treatment as main effect, comparing OV₁ or OV₂, and within treatment group, comparing OV₁ and OV₂. The relative number of follicles per class represent the number of follicles in each class expressed as a percentage of the total number of antral follicles present in the ovary. The diameter of each follicle (as determined by histological observations) was increased by 20% to correct for shrinkage during fixation and embedding (Kruip and Dieleman, 1982; J.G. Lussier and P. Matton, unpublished) to allow comparisons of macroscopic and ultrasonography data. Follicles were reclassified according to macroscopic observations to allow numbers of follicles to be determined histologically, macroscopically and ultrasonographically on day 7 and day 13 to be analysed by
Pearson’s correlation analysis. Precision in the number of follicles estimated by these three methods was calculated by the following equation: \( P = \left\{ 1 - \frac{\sum (Y_i - X_i) \times 100}{\sum Y_i} \right\} \times 100 \), where \( Y_i \) is the number of follicles determined histologically and \( X_i \) is the number of follicles estimated macroscopically or ultrasonographically (Monniaux et al., 1983). One control heifer had to be removed from the analysis because adhesions on the ovaries prevented ultrasonography and ovarioectomy and also because hormonal profiles differed from others in the same treatment group.

Results

Endocrine and ovarian ultrasonography analysis

Intact heifers. Injection of BFF reduced the endogenous circulating FSH concentrations in the BFF-treated heifers from 0.60 ± 0.08 ng ml\(^{-1}\) on day 1 to 0.22 ± 0.05 ng ml\(^{-1}\) on day 7 (Fig. 1). The mean concentration of FSH for the entire period (days 1–7) was lower \((P < 0.04)\) in the BFF-treated group, with an effect of time \((P < 0.0001)\) and a tendency towards a time by treatment interaction \((P < 0.07)\). The mean basal LH concentration from day 1 to day 7 was higher \((P < 0.05)\) in the BFF-treated heifers \((0.81 ± 0.28 ng ml\(^{-1}\))\) compared with controls \((0.34 ± 0.12 ng ml\(^{-1}\))\), but no time or treatment by time interactions were detected. The initial concentration of progesterone \((1.2 ± 1.6 ng ml\(^{-1}\))\) decreased in both groups and reached basal concentrations \((< 0.15 ng ml\(^{-1}\))\); effect of time, \(P < 0.0008\) within 24 h after cloprostenol injection. From day 1 to day 7, the concentration of progesterone remained low and no treatment or treatment by time interactions were observed. Control heifers displayed increasing concentrations of oestradiol from day 1 to day 7 (Fig. 1), but remained constant in BFF-treated heifers \((P < 0.07; \) time and time by treatment interaction\); likewise, the overall mean concentration of oestradiol was higher in control than in BFF-treated heifers \((P < 0.002)\).

The analysis of ovarian ultrasonography data from day 1 to day 7 indicated no significant differences between control and BFF-treated heifers with respect to follicular volume or the number of follicles < 10 mm in the ovary bearing the largest follicle \((OV_1)\) (Figs 2 and 3). However, there was an increase in the follicular volume \((P < 0.03)\) and the number \((P < 0.03)\) of size 4 follicles (>10 mm) in control but not in BFF-treated heifers on days 6 and 7 (Fig. 3). The analysis of total number of follicles between day 1 and day 7 showed an effect of time \((P < 0.02)\), whereas time \((P < 0.05)\) and treatment by time effects \((P < 0.02)\) were observed for the total follicular volume (Fig. 2) in \(OV_1\). No differences were observed between the BFF-treated and control heifers in the number or volume of follicles in \(OV_2\) between day 1 and day 7. The mean diameter of the largest follicle on control \(OV_1\) was 8.0 mm on day 4 and 13.0 mm on day 7, and the mean follicular growth rate was estimated at 1.66 mm day\(^{-1}\).

Hemiovariectomized heifers. Concentrations of FSH after hemiovariectomy (days 8–13) remained low in the BFF-treated...
Concentrations of LH tended to increase in both groups within 36 h of hemicastration, from 0.28 ± 0.12 ng ml⁻¹ to 0.51 ± 0.13 ng ml⁻¹ in controls and from 1.37 ± 0.42 ng ml⁻¹ to 1.71 ± 0.47 ng ml⁻¹ in BFF-treated heifers. The concentration of LH in the BFF-treated heifers following hemicastration had a mean value of 1.57 ± 0.57 ng ml⁻¹ between day 7 and day 13 compared with 1.03 ± 0.46 ng ml⁻¹ in control heifers. Concentrations of LH varied with time (P < 0.02), but no treatment or treatment by time interaction effects were observed. Ten days after removing OV₂, the concentration of LH in controls and BFF-treated heifers rose to 4.84 ± 1.69 and 3.39 ± 1.16 ng ml⁻¹, respectively.

Concentrations of progesterone remained low in both groups and were below the sensitivity limit of the assay.

Concentrations of oestradiol began to rise slightly on day 12 (5 days after hemicastration) in control but not in BFF-treated heifers, so that the mean concentration of oestradiol between day 7 and day 13 was higher (P < 0.01) in control than in BFF-treated heifers (Fig. 1). No effect of time (P > 0.09) or time by treatment interactions (P > 0.16) were noticed. After OV₂ was removed plasma concentrations of oestradiol decreased below the sensitivity limit of the radioimmunoassay in both groups.

The analysis of ovarian ultrasonography data obtained from OV₂ from day 7 to day 13 showed an effect of time (P < 0.03) on the number of size 1 follicles, but no treatment or treatment by time interaction was observed between the control and BFF-treated heifers with respect to the number or volume of follicles (data not shown). There were more size 2 follicles (P < 0.02) in the control than in the BFF-treated heifers on days 10, 11 and 13 (Fig. 3). The number of size 3 and 4 follicles increased within 2 and 4 days of hemicastration, respectively, in control heifers (time by treatment interaction; P < 0.05; P < 0.04), while these types of follicle were completely absent in BFF-treated heifers. When the total number of follicles in BFF-treated and control heifers were compared, an effect of time was observed (P < 0.004), as well as a tendency towards a time by treatment interaction (P = 0.07). Analysis of the follicular volume of size 2, 3, and 4 follicles (Fig. 3) or the total folliculare volume (Fig. 2) displayed treatment (P = 0.03; P < 0.002; P < 0.01; P < 0.0001), time (P < 0.1; P < 0.02; P < 0.08; P = 0.0003) and treatment by time interactions (P < 0.02; P < 0.02; P < 0.08; P < 0.0002). An increase in the volume of size 2 follicles was first detected on day 10 (72 h after hemicastration) and was maintained until day 13, whereas the volume of size 3 follicles began to increase on day 9 (48 h after hemicastration). Follicles >10 mm (size 4) were first observed 4 days after hemicastration (Fig. 3). The total follicular volume of OV₂ (1393.8 ± 276.6 mm³) on day 13 approximated the sum of the follicular volumes of OV₁ (1553.9 ± 149.5 mm³) and OV₂ (104.7 ± 10.4 mm³) that were observed before hemicastration (day 7). The mean diameter of the largest follicle on OV₂ in the five control heifers was 4.2 mm on day 8 and 12.2 mm on day 13, and the estimated mean follicular growth rate was 1.60 mm day⁻¹.
Temporal relationships between the endocrine profiles and the ovarian ultrasound observations

The temporal relationships between the endocrine profiles and the ovarian ultrasonography data in control heifers from day 1 to day 13 were analysed on a within-heifer basis by partial correlation analysis. Negative relationships were found between the concentrations of FSH and oestradiol (\( r = -0.4652, P < 0.0002, \text{d.f.} = 59 \)), and between FSH and the diameter of the largest follicle (\( r = -0.6346, P < 0.0001, \text{d.f.} = 54 \)). The concentrations of oestradiol were positively correlated with the diameter of the largest follicle (\( r = 0.3826, P < 0.004, \text{d.f.} = 54 \)). A negative relationship was found in control heifers between the number and total volume per heifer of size 3 and size 4 follicles (number: \( r = -0.2954, P < 0.02, \text{d.f.} = 54 \); volume: \( r = -0.3600, P < 0.006, \text{d.f.} = 54 \)). Furthermore, a positive relationship was found between the number and volume per heifer of size 1 and size 4 follicles (number: \( r = 0.3218, P < 0.02, \text{d.f.} = 54 \); volume: \( r = 0.2758, P < 0.04, \text{d.f.} = 54 \)). The number and volume of size 1 (\( r = -0.2919, P < 0.03 \)), size 3 (\( r = -0.367, P < 0.005 \)), size 4 (\( r = -0.3479, P < 0.009 \)) and size 4 (\( r = -0.3229, P < 0.01 \); \( r = 0.2857, P < 0.03 \)) follicles were negatively correlated with the concentrations of FSH. A positive correlation was observed between the number and volume of size 1 (\( r = 0.3792, P < 0.004 \); \( r = 0.3786, P < 0.004 \)) and size 4 (\( r = 0.4189, P < 0.001 \); \( r = 0.3853, P < 0.003 \)) follicles and the concentration of oestradiol.

Analysis of ovarian macroscopic and histological observations

Macroscopic observations of the ovaries bearing the largest follicle (OV\(_1\)) on day 7 following 6 days of treatment showed that there were fewer size 4 follicles in BFF-treated heifers than in control heifers (Table 1); in addition, size 4 and total follicular volumes (data not included) were lower in the BFF-treated ovaries. Control ovaries on day 13 (OV\(_2\)) contained large, hyperaemic follicles, whereas the BFF-treated ovaries appeared yellowish with minimal vascularization and had no follicles \( \geq 7 \) mm in diameter. BFF-treated heifers had fewer follicles of size 2 (\( P < 0.1 \)), 3 (\( P < 0.01 \)) and 4 (\( P < 0.01 \)) on OV\(_2\). Follicular volume was also lower in follicles of sizes 3 and 4, as was the total follicular volume per ovary, compared with control ovaries. More size 3 follicles were found on OV\(_2\) than on OV\(_1\) from control heifers. In the BFF-treated heifers, a smaller total follicular volume was found in OV\(_2\) compared with OV\(_1\); this was mainly related to fewer follicles \( > 4 \) mm in diameter (data not included).

Number of follicles in control and BFF-treated heifers were compared for each follicular size at day 7 or at day 13 (*\( P < 0.05 \); \( ^a P < 0.01 \); \( ^b P < 0.1 \)).

Analysis of the ovarian histological data showed no statistical differences between the control OV\(_1\) or the BFF-treated OV\(_1\) on day 7 for follicles \( \leq 8.57 \) mm in diameter (Table 2). The absolute or relative number and volume (data not included) of follicles \( > 8.57 \) mm was lower in the BFF-treated OV\(_1\) ovary. Comparison with OV\(_2\) on day 13 showed no difference in follicles from classes 2, 3 or 4. More atretic class 5 follicles relative to the total number of follicles per ovary were found in the BFF-treated OV\(_2\) (\( P < 0.05 \)).

Classification of these atretic follicles suggested a more advanced atresia in follicles from BFF-treated heifers. Lower absolute (Table 2) or relative numbers and volumes of class 6 and 7 follicles were found in the BFF-treated OV\(_2\) than in control ovaries. When ovaries taken from control heifers on day 7 and day 13 were compared a greater absolute or relative number (\( P < 0.05 \); \( P < 0.01 \)) and volume (\( P < 0.01 \)) of class 6 follicles on OV\(_1\) was observed compared with OV\(_1\). However, this increase in the total number and volume of follicles is mainly due to an increase in atretic follicles. Total follicular volume in class 7 of OV\(_1\) was higher than that of OV\(_1\) in control heifers and this difference was associated with follicles in the late stages of atresia on OV\(_2\). No differences were found when OV\(_1\) and OV\(_2\) from BFF-treated heifers were compared for follicles \( < 3.68 \) mm in diameter. For follicles \( \geq 3.68 \) mm, the absolute number of follicles and follicular volumes were less (\( P < 0.01 \); \( P < 0.05 \)) in OV\(_2\) than in OV\(_1\). Positive correlations were found between the observations obtained macroscopically, histologically and by ultrasound scanning on OV\(_1\) and OV\(_2\), with an average overall precision of 51.3\% between the ultrasound and macroscopic observations (\( r = 0.591, n = 22, P < 0.002 \)), 45.1\% between the ultrasound and histological observations (\( r = 0.6155, n = 22, P < 0.001 \)) and 72.3\% between the macroscopic and histological observations (\( r = 0.9656, n = 22, P < 0.0001 \)).

Discussion

Injection of charcoal-extracted BFF effectively reduced the circulating FSH concentrations in intact and hemiovarectomized postpuberal heifers. The concentration of FSH

A₁: atresia level 1; A₂: atresia level 2; A₃: atresia level 3; N: normal; Total: total number of normal and atretic follicles per histological class.

The absolute number of follicles were compared between control and BFF-treated ovaries (OV₁ versus OV₂, and OV₂ versus OV₃).

*P < 0.05; **P < 0.01; †P < 0.1 and within control or BFF-treated ovaries (OV₁ versus OV₂; †P < 0.05; ‡P < 0.01).

Decreased by 31–40% within 12–24 h following the first injection of BFF, and remained low during the 12 days of treatment. The suppression of circulating FSH in this experiment corresponds to the 30–45% decrease in the FSH concentration obtained in previous experiments in intact heifers (Lussier and Carruthers, 1989; Wood et al., 1993), in ovarioectomized heifers injected with the 32 kDa bovine inhibin molecule (Beard et al., 1990), and to the 30–40% maximal suppression of FSH release by BFF in dispersed bovine pituitary cells (Lussier et al., 1993). Since the radioimmunoassay reflects immunoreactive concentrations of FSH, it cannot be determined if the residual circulating FSH concentration after BFF treatment has an altered bioactivity (Dahl et al., 1988; Wilson et al., 1990; Robertson et al., 1991).

The mean basal concentrations of LH from day 1 to day 7 were higher in BFF-treated than in control heifers; this is in contrast to previous experiments in which no such increase was detected (Lussier and Carruthers, 1989; Moser et al., 1989; Turzillo and Fortune, 1993). The major difference in this experiment is that a synthetic progesterone analogue, Norgestomet, was used to prevent ovulation after induction of luteolysis, whereas the corpora lutea had been left intact in previous experiments. The Norgestomet implant may have had a less stringent negative feedback on LH secretion, as
suggested by previous studies (Kojima et al., 1992; Stock and Fortune, 1993), thereby allowing small changes in the steroid metabolism of the follicles to influence the activity of the hypothalamo–pituitary axis. The decrease in follicular development induced by the BFF injections, together with a lower concentration of oestradiol found in this group of heifers, supports a decreased negative feedback on LH secretion, and suggests that BFF overrides the effects of an increased concentration of LH on follicular development.

Injection of BFF into heifers for a period of 6 days altered follicular development. Ultrasonographical results showed that a decrease in the volume of follicles >10 mm on the ovary bearing the largest follicle occurred after 6 days of BFF injections. Follicular development in control heifers was characterized by the growth of follicles >10 mm in diameter and an increase in the oestradiol concentration. The lack of an increase in the concentration of oestradiol in BFF-treated heifers reflects altered follicular development. The scheme for synchronization of oestrus in the present experiment and the use of the Norgestomet implant may have altered normal follicular development by causing follicular persistency (Stock and Fortune, 1993). Despite the fact that follicular status was not monitored before the experiment, BFF prevented the development of follicles in all treated cows.

The histological studies are in agreement with the macroscopical and ultrasonographical observations: only the frequency of class 7 follicles (>8.57 mm) was lower in BFF-treated heifers. No effects were detected on numbers of follicles or their status if they were ≤8.57 mm. Our follicular data suggest that BFF reduced or limited the growth of follicles in large size classes. Although no morphological effects were seen on the number or the atresia status of follicles ≤8.57 mm, we cannot conclude that follicles ≤8.57 mm were not metabolically altered by the presence of exogenous BFF. In heifers that were superovulated immediately after 6 days of BFF treatment, a decrease in the mean number of corpora lutea, a smaller size of corpora lutea, and a 24 h delay in the preovulatory gonadotrophin surge were observed (Lussier and Carruthers, 1989). These results indicated that at the time superovulation was initiated the target follicular pool was decreased in BFF-treated heifers, and that follicles began their growth from a probable follicular pool of <3–4 mm.

After hemiovariectomy, the concentration of FSH in control heifers increased, reached a maximum at 36 h and then decreased, whereas in BFF-treated heifers FSH remained suppressed. Thus, the concentration of polypeptides (i.e. inhibin and follistatin) in the injected BFF was sufficient to overcome the effects of decreased ovarian endogenous negative feedback following hemicastration. Circulating concentrations of basal LH in both groups had a tendency to increase after hemicastration, which supports the premise that a reduced negative feedback due to reduced steroid concentrations is brought about by the removal of OV1 and the less stringent negative feedback of Norgestomet. However, owing to the pulsatile nature of LH release and our infrequent blood sampling, no clear conclusion was reached.

In control heifers, follicular development as monitored by ultrasonography showed a compensatory response over time from day 7 to day 13 in follicles ≥4 mm in diameter. The increase in the number of follicles 4–6 mm in diameter was first observed on day 10 (72 h after hemiovariectomy), and was subsequently observed in larger size classes. Moreover, a small initial increase in the concentration of oestradiol was detected on day 12 (i.e. 5 days after hemiovariectomy), concomitant with the appearance of follicles >10 mm in diameter. The circulating oestradiol concentrations observed were similar to those observed by Staigmiller and England (1982), who measured the concentrations of oestradiol in follicular fluid of growing follicles 4 days after cauterizing all follicles >5–6 mm. They concluded that 4 days after cauter, neither the size of the largest follicle nor production of oestradiol in the follicular fluid were indicative of a preovulatory follicle.

The compensatory process as detected by ultrasonography, and the FSH and oestradiol endocrine profiles suggest that after the ovary bearing the largest follicle is removed, ovarian inhibitors (polypeptides or steroids) are cleared from the circulation, allowing the circulating concentration of FSH to increase. This rise in FSH stimulates the development of small follicles <4 mm in diameter within 36 h after hemiovariectomy, which is subsequently revealed in time in size 2, 3 and 4 follicles. The concentration of FSH began to decrease between 48 and 60 h after hemiovariectomy, before or at the time we observed an increase in the 7–10 mm follicles. Thereafter, the concentration of FSH decreased as more large follicles appeared (>7 mm in diameter). An increase in the concentration of oestradiol on day 12 reflects the initial presence of large active and mature follicles (>10 mm) in control heifers. In control heifers, the negative correlations between the FSH concentration and the circulating oestradiol concentration or the mean diameter of the largest follicle support the concept that factors produced by a large dominant follicle control the circulating concentration of FSH (Lussier and Carruthers, 1989; Martin et al., 1991; Kaneko et al., 1991, 1992, 1993; Adams et al., 1992; Guilbault et al., 1992; Turzillo and Fortune, 1993).

Macroscopic and histological observations on day 13 correspond to the ultrasound observations and showed a compensatory response in the control heifers, with the presence of large follicles (≥7 mm) 6 days after hemiovariectomy. These results are in agreement with the results obtained in cyclic cattle (Saiduddin et al., 1970) and prepubertal heifers (Johnson et al., 1985; Moser et al., 1989). However, the macroscopic observations on day 13 do not indicate from which follicular pool follicles were recruited to compensate for the loss of one ovary. Since antral follicle populations ≤8.57 mm are similar between ovaries (cow: Monniaux et al., 1983; Lussier et al., 1987; monkey: Koering, 1987), comparing histological data for OV1 and OV2 within control heifers indicated similar numbers of follicles >8.57 mm or <3.68 mm; however, follicles 3.68–8.57 mm in diameter were more numerous on OV2. Thus, the ovarian compensatory processes occurred by an increase in the number and volume of medium-sized follicles (3.68–8.57 mm). The large number of follicles <3.68 mm and the estimated growth rate of 4 days to grow from 0.67 to 3.67 mm (Lussier et al., 1987) may have masked differences in the numbers of follicles in these classes, which would explain the growth of follicles <3.68 mm in diameter into the larger size class (≥3.68 mm). The negative correlation found in control heifers between follicles >10 mm and the 7–10 mm follicles suggests...
that the presence of large follicles inhibits the growth of 4–6 mm follicles into the 7–10 mm follicular pool.

The increase in the overall follicular diameter from 3.68 to 8.57 mm in OV2, in control heifers is mainly due to an increase in atretic follicles, indicating that follicular selection is present even during the compensatory response; this is consistent with the normal ovulation rates seen after hemiovariectomy (Saiduddin et al., 1970; Merz et al., 1977; Grass and Hauser, 1981). An increase in the number of atretic follicles in control OV2 on day 13 may be attributed to the decrease in circulating FSH concentrations caused by increased follicular development and negative feedback. However, as the basal LH concentration was higher at this time compared with the initial concentration at the beginning of the experiment, increased basal LH concentrations associated with low FSH concentrations may also have contributed to atresia (McNeilly, 1991). Increased atresia in follicles between 3.68 mm and 8.57 mm is in agreement with the hypothesis of a selective follicular process that reduces the number of growing follicles in the final stage of follicular development and leads to follicular dominance in cattle (Adams et al., 1992; Turzillo and Fortune, 1993).

Injection of BFF inhibited the recruitment and development of follicles following hemiovariectomy. Histological data showed an absence of or a reduced number of follicles ≥3.68 mm in the BFF-treated OV2 compared with controls, but no effects were observed on the number of follicles <3.68 mm. It has been shown that bovine follicles <3.68 mm express the FSH receptor (Wandji et al., 1992). It is thus conceivable that while small antral bovine follicles could be less susceptible to a low concentration of FSH and can maintain their metabolic activities without becoming atretic in this hormonal milieu, such a hormonal condition is detrimental to the survival of follicles ≥3.68 mm in diameter.

The largest follicles on OV2 between day 1 and day 7 and on OV2 between day 7 and day 13 in control heifers had a similar mean growth rate (1.6 mm day⁻¹). These estimated growth rates for medium–large sized follicles (i.e. ≥4 mm) are in agreement with histological (Lussier et al., 1987) and ultrasonographical observations (Quirk and Fortune, 1980; Sinois and Fortune, 1988; Knopf et al., 1989; Kastelic et al., 1990) obtained at different times of the oestrous cycle. If follicles are recruited at <4 mm and if their growth rate is around 1.6 mm per day, at least 2 days would be required for a follicle to reach 7.2 mm. This estimation corresponds to our ultrasonography data, as more follicles of diameter 4–6 mm were observed approximately 2 days after circulating FSH concentrations reached a maximum, and it also agrees with the observations of Adams et al. (1992) from intact BFF-treated cows. There is a similarity between the increased postovulatory FSH rise during the oestrous cycle and the posthemiovariectomized FSH rise. The postovulatory increase in the FSH concentration is necessary to recruit the dominant follicle that reaches its maximum size on day 7–8 of the oestrous cycle (Turzillo and Fortune, 1990). As the postovulatory FSH rise is detected approximately 48 h after the preovulatory gonadotrophin surge, if follicles >3–4 mm are atretic during this period, and recruited follicles <4 mm are growing at a rate of 1.6 mm day⁻¹, the diameter of the first dominant follicle should be about 9–12 mm on days 6–8. This is a similar value to the maximum diameter reached and observed by ultrasonography (Sirois and Fortune, 1988; Turzillo and Fortune, 1990, 1993; Adams et al., 1992).

We observed that follicular recruitment and development beyond a diameter of 3.68 mm in cattle depends on an adequate circulating concentration of FSH. The results reported here indicate that polypeptides present in BFF inhibit follicular development by acting on the pituitary to reduce the release of FSH (Lussier and Carruthers, 1989; Moser et al., 1989; Adams et al., 1992; Lussier et al., 1993; Turzillo and Fortune, 1993; Wood et al., 1993). Kaneko et al. (1993) observed an increase in the number of follicles 4–7 mm in diameter 48 h after passive immunization against inhibin. Their results support the concept of a physiological blockade of follicular development beyond growth to 3.68 mm through the action of inhibin at the pituitary to reduce FSH synthesis and release. Results obtained in cattle (Law et al., 1992) and in sheep (Larson et al., 1991) suggest that polypeptide factors present in BFF may also alter follicular development by acting directly on the ovary. However, a direct effect of BFF on cow ovaries was not supported by the results of Moser et al. (1989). Thus, the design of the present experiment cannot rule out a possible direct effect of BFF on the ovary or that polypeptide factors present in BFF contributed to an alteration in follicular growth. Both mechanisms of action are possible, indirect (mediated through the pituitary) or direct (mediated through the ovary), but the relative importance of each mechanism remains to be determined.

Granulosa cell mitotic activity increases significantly in follicles 0.68–3.67 mm in diameter, at which time a marked increase in antrum size relative to the granulosa layer occurs (Lussier et al., 1987). The ovarian histological data of the present experiment showed that atresia of 9.5% in class 3 (0.29–0.67 mm) follicles increased to 36.1% (excluding atresia status 1) in class 4 (0.68–1.52 mm) follicles. These data are in agreement with our previous results (Lussier et al., 1987). In follicles ≥3.68 mm in diameter, an increase in atretic follicles of up to 86.9% was observed. It is also at this stage that inhibition of follicular growth by BFF occurs. With these results and the model proposed by Hirshfield (1991) in rats, we postulate that follicles of 0.68–3.67 mm in diameter displaying increased granulosa cell mitotic activity associated with a markedly increased antrum size are prevented from entering their final stage of differentiation by a lack of FSH. This final differentiated state of granulosa cells may induce increased follicular metabolic requirements to support and sustain the final and rapid follicular growth; otherwise, the follicle becomes atretic. FSH would stimulate entry into and sustain the growth of follicles beyond the 3–4 mm stage. A decrease in the circulating concentration of FSH by a growing dominant follicle would therefore precipitate atresia in follicles that are >3–4 mm owing to the lack of adequate FSH support (Zeleznick and Cubic, 1986; Adams et al., 1992; Turzillo and Fortune, 1993).
