Long-term influence of sialoadenectomy on reproductive performance of male mice

A. B. V. Reyes and N. Wakasugi*

Laboratory of Animal Reproduction, School of Agricultural Sciences, Nagoya University, Furo-cho, Chikusa-ku, Nagoya, 464, Japan

The influence of the submandibular gland, the major source of epithelial growth factor, on male reproduction in mice was studied by removing the submandibular gland (sialoadenectomy) and examining its effects on sperm production and copulation and fertility rates over an extended post-operation period. The removal of the submandibular gland caused a decrease in the number of epididymal spermatozoa 4 weeks after the operation; the decrease became significant ($P < 0.05$) 6–10 weeks after the operation compared with the sham operated and intact groups. There was no significant difference between prepuberal (30 days old) and postpuberal (60 days old) sialoadenectomy, indicating that the submandibular gland is not related to the maturation of the seminiferous tubules. The reduction in the number of epididymal spermatozoa was due to the decrease in number of spermatogonia and spermatoctyes per Sertoli cell in the seminiferous tubules. When the reproductive performance was examined over 14 weeks, sialoadenectomized males showed a lower copulation rate and a significantly ($P < 0.05$) higher incidence of non-fertile copulation compared with the sham-operated and intact males. These results indicate that the submandibular gland and the secretion of epithelial growth factor from it affect spermatogenesis by acting on spermatogonial proliferation and sperm maturation.

Introduction

Epithelial growth factor (EGF) receptors have been shown to be present in the Leydig cells and Sertoli cells of adult mouse testes (Suarez-Quian and Niklinski, 1990; Suarez-Quian et al., 1994), in the epididymis and vas deferens of non-human primates (Radhakrishnan and Suarez-Quian, 1992), as well as in the prostate glands of rats (Traish and Wotiz, 1987), indicating that EGF has some effects on male reproduction. EGF has been shown to interact with testosterone in the differentiation and development of the Wolffian duct (Gupta et al., 1991; Gupta and Jaumotte, 1993), and to participate in the regulation of androgen synthesis (Verhoeven and Cailleau, 1986; Sordoillet et al., 1991) and stimulation of sperm capacitation (Furuya et al., 1993). In mice, the submandibular gland is the major source of EGF (Barka, 1980) and the EGF content of the gland gradually increases from 0.02 ng mg$^{-1}$ wet tissue at 15 days of age to 0.30 ng mg$^{-1}$ at 20 days, 47 ng mg$^{-1}$ at 29 days, reaching a maximum of about 1000 ng mg$^{-1}$ at 50 days (Byyny et al., 1972). This increase in the EGF content of the submandibular gland is related to sexual maturation and has been shown to be androgen dependent (Byyny et al., 1974).

The removal of submandibular gland (sialoadenectomy) results in a reduction in the number of epididymal spermatozoa (Tsutsumi et al., 1986; Russell et al., 1990). On the basis of these and other findings, the existence of a submandibular gland–gonadal axis that controls spermatogenesis has been suggested by Tsutsumi et al. (1986) and Noguchi et al. (1990). However, Tokida et al. (1988) found no significant difference in fertility rate between sialoadenectomized and sham-operated male mice, and concluded that the submandibular gland has no role in reproductive function in male mice.

The present report provides additional evidence showing that the submandibular gland is related to the spermatogenic activity in mice. The reduction in both the number of epididymal spermatozoa and fertility in sialoadenectomized male mice could be significant if observation is made over an extended period of time.

Materials and Methods

Animals and treatments

ICR mice (ICR:slc) purchased from Shizuoka Laboratory Animal Corporation, Shizuoka, Japan and their descendants were used for the present study. They were kept under controlled conditions (22 ± 2°C and under a photoperiod of 14 h light:10 h dark) and given the commercial pellet diet (CA-1; Clea Japan Inc., Tokyo) and water ad libitum.

Ninety males, aged 30 days, were randomly placed into one of three groups, sialoadenectomized, sham-operated or intact groups. Sialoadenectomy or the sham operation were carried out at 30 days of age (prepuberal sialoadenectomy). After the experimental animals were anaesthetized with diethyl ether
(Yoneyama Yakuhin Company, Osaka), an incision was made in the ventral portion of the cervical region to open the skin. For the sialoadenectomized group, the submandibular glands were removed after ligating two parallel vessels entering the glands, the glandular branches of the external maxillary artery and anterior facial vein, while for the sham-operated group, the submandibular glands were manipulated without removing them. Six mice from each group, of approximately the same body mass, were used for the sperm count and histological examination of testes 2, 4, 6, 8 and 10 weeks after the operation. Another set of 18 males underwent sialoadenectomy at the age of 60 days and groups of six males were killed by cervical dislocation at the age of 75, 90 and 105 days to compare the effects of prepuberal and postpuberal sialoadenectomy.

Number of spermatozoa

The number of spermatozoa in the epididymides was determined according to the method of Taylor et al. (1985). The epididymides were removed, weighed, finely minced and placed in 2 ml of 0.9% (w/v) NaCl. The number of spermatozoa in seven chambers of a haemocytometer were counted, the highest and lowest scores were discounted and the number of spermatozoa was calculated from the counts in the five chambers. Two counts were made for each epididymis. The number of epididymal spermatozoa of a male was expressed as the mean of the counts from left and right epididymides.

Examination of the seminiferous tubules under the microscope

The left and right testes were weighed and fixed overnight in Bouin’s solution. Fixed tissues were embedded in paraffin wax, sectioned at 6 μm and stained with haematoxylin and eosin. The spermatogenic activity was estimated as the 'Sertoli Cell Ratio' as described by Gosden et al. (1982). For each male, 20 seminiferous tubules at stages II–V1 with approximately circular cross-section were randomly selected. The number of spermatogonia, spermatocytes and early spermatids in those tubules was counted under oil immersion (×1000) and expressed as a ratio to the number of Sertoli cells in the same tubule.

The diameter of the seminiferous tubule was represented by the shorter diameter of the tubules (20 tubules per animal) used to count the germinal cells. The tubular lumen was measured for the stage VII seminiferous tubule (20 tubules per animal).

Fertility of sialoadenectomized and sham-operated mice

A fertility test was carried out on mice that underwent sialoadenectomy or the sham-operation at 30 days of age, one month after the operation. Female mice were caged individually with the males between 14:00 and 15:00 h on day 1. Females were examined for the presence of a vaginal plug every morning until day 6. Females with a vaginal plug were kept separately until parturition. Pregnancy was confirmed either by a vaginal haemorrhage 11–12 days after copulation or by an increase in body mass. Females with no vaginal plug were caged individually for 2 weeks and, after being confirmed as not pregnant, they were used for the next experiment. Males underwent the fertility test for 14 consecutive weeks.

Statistical analyses

Comparison of the Sertoli cell ratio between groups was carried out by the Wilcoxon's test as described by Gosden et al. (1982) and other group comparisons were made by analysis of variance or Student's t test. Mean comparison was made by Duncan's Multiple Range Test. The linear relationship between body mass and number of spermatozoa was determined by correlation and regression analysis.

Results

The removal of the submandibular gland at 30 days of age resulted in a lower body mass (Fig. 1) and a significant difference ($P<0.01$) was noted between the sialoadenectomized and intact groups 6 weeks after the operation and between the sialoadenectomized group and both control groups (sham-operated and intact) ($P<0.05$) at 10 weeks. The sham-operated mice consistently had a lower body mass than did the intact mice but the difference was not significant ($P>0.05$). It is interesting that the sialoadenectomized mice had lower body mass as their feed intake was higher than the other groups. When measured up to 9 weeks after the operation, sialoadenectomized mice ($n=4$) had a mean feed intake of 47.8 g per week while the sham-operated mice ($n=5$) had an intake of 41.2 g per week.

The number of epididymal spermatozoa in prepuberal sialoadenectomized males was consistently lower than in the sham-operated and intact males at 2, 4, 6, 8, and 10 weeks after the operation (Fig. 2). With the exception of the second week,

Fig. 3. Comparison of number of epididymal spermatozoa between (■) prepuberal and (□) postpuberal sialoadenectomized ICR mice. No significant difference (P > 0.05) was noted at any stage between the two groups. Figures within bars are the times (days) after sialoadenectomy.

The difference was approximately 20% and the difference was significant (P < 0.05) after 6 weeks. A comparison of the effect of prepuberal (at 30 days) and postpuberal (at 60 days) sialoadenectomy on number of spermatozoa showed no significant difference (Fig. 3). The sperm count was carried out at 75, 90 and 105 days of age, regardless of the time of sialoadenectomy; therefore, the prepuberal data correspond to the measurements at 6, 8 and 10 weeks after the operation (as shown in Fig. 2).

A correlation analysis was made between body mass and epididymal sperm count 10 weeks after the operation to determine whether the difference in body mass had an influence on the epididymal sperm count. There was no significant correlation between the two variables in any of the males in the three experimental groups (Fig. 4).

Representative histological micrographs of the seminiferous tubules from sialoadenectomized and sham-operated mice and each representative cell type counted in the present study are shown (Fig. 5).
size of the seminiferous tubules, but there was no apparent effect on the size of the tubular lumen (Table 2). The number of Sertoli cells was not affected by the removal of the submandibular gland.

The reproductive performance of the three groups of males, mated with a female once a week for 14 consecutive weeks is shown (Table 3). A decrease in the reproductive performance of sialoadenectomized mice was observed; the numbers of copulations and pregnancies were lower when compared with results from sham-operated and intact males. Furthermore, a significant ($P < 0.05$) difference was noted in the pregnancy rate between the sialoadenectomized and intact groups. These findings are consistent with the reduction in the Sertoli cell ratio of germinal cells in the sialoadenectomized males. Litter size was similar in all three groups. When analysed on a per month basis, all the three groups showed a progressive reduction in the total pregnancy rate but the lowest rate was consistently observed in the sialoadenectomized group (Fig. 6).

**Discussion**

A reduction in the number of epididymal spermatozoa after the removal of the submandibular gland has previously been reported in mice. Tsutsumi et al. (1986) observed a 40–50% reduction while Russell et al. (1990) noted only a 10% reduction in the number of spermatozoa. In these experiments, sialoadenectomy was carried out at 14 weeks of age, and the number of epididymal spermatozoa was counted 4 weeks after the operation. In the present study, sialoadenectomy was performed at 30 days of age when salivary EGF content is low: approximately 47 ng mg$^{-1}$, well below the maximum of about 1000 ng mg$^{-1}$ observed in mature male mice (Byyny et al., 1972). This prepuberal sialoadenectomy resulted in about a 20% reduction in the number of epididymal spermatozoa 4 weeks after the operation and the reduction was significant ($P < 0.05$) 6–10 weeks after the operation. However, there were no significant differences in the number of epididymal spermatozoa between prepuberal and postpuberal sialoadenectomized mice at 75, 90 and 105 days of age. This finding and the presence of normal seminiferous epithelium at 45 days of age after prepuberal sialoadenectomy at 30 days indicate that the submandibular gland has no apparent contribution to the maturation of seminiferous tubules, despite the increase in EGF synthesis in the submandibular gland resulting from increasing androgen production during this period.

Peerheentupa et al. (1984) reported a lower body mass among sialoadenectomized mice, indicating that the removal of the submandibular gland has a significant effect on growth. Similar growth suppression or retardation was seen in the present study. However, this inhibition of growth had no effects on the number of epididymal spermatozoa as shown by the absence of correlation between the two variables. It is interesting, however, that the sialoadenectomized mice had lower body mass despite a higher feed intake. One possible explanation of the growth inhibition is that there is a reduction in growth hormone secretion as a result of lower EGF concentrations (Ikeda et al., 1984).

Tsutsumi et al. (1986) reported that sialoadenectomy causes an increase in the number of primary spermatocytes and...

*Sialoadenectomy was carried out at 30 days of age and the cellular composition was examined at 80 days of age. The Sertoli cell ratio is shown as the ratio of number of germ cells to the number of Sertoli cells in the same seminiferous tubule segments and the values are shown as medians and ranges.

*These values are significantly different from those of the sham-operated and intact groups (P < 0.01; Wilcoxon’s test).

a reduction in the number of round spermatids, indicating a disturbance of the meiotic division in spermatogenesis. Suarez-Quian et al. (1994) however, suggested that the fall in plasma EGF concentrations after sialoadenectomy in adult male mice leads to a diminution in spermatogonial mitotic activity in the basal compartment of the seminiferous epithelium. This suggestion is supported by the finding in the present study that the number of spermatogonia per Sertoli cell was significantly lower in the sialoadenectomized mice compared with the sham-operated and intact mice. This is consistent with the finding of Bartlett et al. (1990) that the concentration of EGF in the stage-synchronized rat testes increases at stages IX–I of the seminiferous tubule cycle, corresponding to the mitotic division of type A spermatogonia at stages IX, XII and XIV. In addition, EGF induces differentiation of type A spermatogonia in vitro (Haneji et al., 1991). In the present study, the reduction in the number of epididymal spermatozoa due to prepuberal sialoadenectomy was observed 4 weeks after the operation. Since spermatogenesis in mice takes approximately a month for completion (Clermont and Trott, 1969), the reduced number of spermatozoa after sialoadenectomy is thought to be attributed to fewer spermatogonia undergoing differentiation into the spermatocyte stage approximately a month before. It is necessary to mention here that the use of the ‘Sertoli cell ratio’ as a method of quantifying the germinal cells in the present study is based on the fact that sialoadenectomy does not cause any reduction in the number of Sertoli cells per seminiferous tubule and hence the ratio can be used as an indicator of the spermatogenic activity of the testis (Skakkebaek and Heller, 1973).

The reduction in the number of germinal cells per Sertoli cell was accompanied by a significant reduction in the size of the seminiferous tubules. A similar reduction in the tubule diameter of mice has been observed when the number of spermatids was reduced (Tajima et al., 1991). However, no significant reduction in the lumen size was observed in the present study.

Sialoadenectomy resulted in not only a reduced copulation rate, but also a significant reduction in the pregnancy rate, that is, a higher incidence of non-fertile copulation. This higher incidence of non-fertile copulation could be attributed to the oligozoospermic condition resulting from EGF deficiency (Noguchi et al., 1990) or a reduction in secretion from seminal vesicles which would cause a fall in the number of spermatozoa transported to the uterus (Carballada and Esponda, 1992). The mass of the seminal vesicles of sialoadenectomized mice was lower than that of the sham-operated group (136 mg versus 211 mg) at 90 days. In a mating experiment with sialoadenectomized DDY males and normal females in which the cohabitation period was short (36–48 h), Tokida et al. (1988) found no significant reduction in the pregnancy rate. In the present study, reproductive function of the sialoadenectomized mice was examined for 14 consecutive weeks, and significant reduction in reproductive performance was observed. It is worth noting that the pregnancy rate for the three groups in the present study was similar for the first exposure to female mice, coincident with the finding of Tokida et al. (1988). As the mating experiment progressed, there was a general decrease in the pregnancy rate in all three groups; however, the reduction was greatest in the sialoadenectomized group and this was particularly noticeable when the pregnancy rate was calculated for the entire experimental period. This accelerated and progressive reduction in reproductive performance may reflect a progressive decline in germinal epithelial activity, since a major role of EGF in adult mammals is thought to be the maintenance of epithelial surface function (Fisher and Lakshmanan, 1990).

The reduction in number of spermatozoa (about 10%) observed by Russell et al. (1990) in C3H males 4 weeks after the operation was not significant. As mentioned earlier, Tokida et al. (1988) observed no significant difference in the

Fig. 6. Total number of females impregnated per month by (■) sialoadenectomized, (□) sham-operated and (△) intact ICR male mice. Males were caged individually with females for a maximum pairing period of 6 days. Five males were used in each group, therefore, maximum possible number of pregnant females is 20.

reproductive performance between sialoadenectomized and sham-operated DDY mice after cohabitation for 36–48 h. Our results on the reproductive performance of sialoadenectomized mice observed for 14 weeks showed significantly lower fertility rates when compared with sham-operated and intact males, indicating a long-term effect of sialoadenectomy. However, it is possible that the difference between our results and the other reports may be due to the difference in mouse strains used.

Salivary EGF directly stimulates spermatogonial proliferation (spermatocytogenesis) and its production by the submandibular gland is under the influence of testosterone, while secretion of EGF is under the control of the sympathetic nervous system (Byyny et al., 1974). However, the removal of the submandibular gland does not result in complete cessation of spermatogonial cell proliferation. Possible explanations for this could be: (1) EGF may be produced by other organs (Byyny et al., 1972). This was confirmed in the study of Tokida et al. (1988), in which sialoadenectomy performed in DDY mice resulted in lower concentrations but not total loss of EGF; (2) other growth factors of testicular origin affect mitotic activity in the seminiferous tubules (Bellve and Zheng, 1989); and (3) substances like activin and inhibin participate in the control of spermatogenesis (Mather et al., 1990; Van Dissel-Emiliani et al., 1989).
