A potential role for insulin-like growth factor I (IGF-I) in the regulation of the uterine electrolyte environment was studied in conjunction with hyperoestrogenaemia caused by superovulation. Uterine luminal fluid from immature rats treated with 4 (control), 10, 20 and 40 IU (superovulation) pregnant mares’ serum gonadotrophin (PMSG, day −2) and the electrolyte composition was determined on day 3 of pregnancy. Superovulation increased total cation content in uterine flushes by more than twofold, suggesting a comparable increase in the uterine luminal fluid volume. Percentages of K⁺ and HCO₃⁻ content to total cations or anions increased by 27% and 16%, respectively, and those of Na⁺ and Cl⁻ decreased by 26% and 15%, respectively, after superovulation. Daily injections with 1.0 μg or more oestradiol, from day 0 to day 2, in the 4 IU PMSG-primed immature rats caused similar changes in total cation content and electrolyte composition of uterine luminal fluid.

Anti-IGF-I antibody infusion in the superovulated or oestradiol-treated immature rats restored the alterations in cation composition but had no effect on anion composition and total cation content. IGF-I was infused into adult rats to achieve increased IGF-I action observed after superovulation. IGF-I infusion altered electrolyte composition, as is observed after superovulation or oestradiol treatment, but had no effect on total cation content. In conclusion, hyperoestrogenaemia caused by superovulation may alter the uterine electrolyte environment for preimplantation embryonic development. IGF-I appears to play a central role in mediating this action of oestrogen.

Introduction

Hyperoestrogenaemia caused by superovulation appears to be responsible for many detrimental effects of superovulation including early embryonic loss (Moon et al., 1990). Increased insulin-like growth factor I (IGF-I) action, caused by hyper-oestrogenaemia resulting from superovulation renders the uterine environment hostile to embryonic development in rats (Katagiri et al., 1996). The same study also found that the uterine luminal fluid is no longer detrimental to embryonic development after the fluid is dialysed against conventional culture media.

Evidence suggests that the uterine electrolyte environment is under the influence of ovarian steroid hormones (Kao, 1967; Setty et al., 1973; Van Winkle et al., 1983). In general, the electrolyte environment plays a critical role in maintaining cellular homeostasis and regulating cellular metabolism. Alterations in the electrolyte composition of culture media results in retardation of embryonic development or embryonic loss (Van Winkle, 1977; Schini and Bavister, 1988; Seshagiri and Bavister, 1991; Lawitts and Biggers, 1992; Dumoulin et al., 1993). These observations lead us to the hypothesis that alterations in the electrolyte composition of the uterine environment may be a factor that renders the uterine environment detrimental to preimplantation embryonic development.

Despite the importance of the electrolyte environment on preimplantation embryonic development, no study has attempted to determine the endocrine/paracrine regulation of the electrolyte composition of uterine luminal fluid. IGF-I is one of many growth factors that mediate the actions of ovarian steroid hormones in the uterus (Murphy and Ballejo, 1994). The present study examined a potential role for IGF-I in mediating oestrogen action on uterine electrolyte environment, in conjunction with hyperoestrogenaemia caused by superovulation. To our knowledge this is the first study demonstrating a role for growth factors in the regulation of electrolyte environment for preimplantation embryonic development.

Materials and Methods

Anti-IGF-I antibody preparation

Rabbit anti-IGF-I antiserum (Amersham Canada, Oakville, Ontario) was diluted (1:1 v/v) with 100 mmol phosphate

buffer $1^{-1}$ (pH 7.0) and applied to a protein A column (Bio-Rad, Mississauga, Ontario). Antibody was eluted with 1 mol acetic acid $1^{-1}$ and the eluate from the protein A affinity column was then applied to a Sephadex G-25 column. The antibody solution eluted in 100 mmol phosphate buffer $1^{-1}$ (pH 7.4) was concentrated and an aliquot was subjected to protein assay (Lowry et al., 1951).

**Animal treatments**

All animals were purchased from the Animal Care Centre at the University of British Columbia (Vancouver, BC) and maintained at 23–25°C with a 14 h light (05:00–19:00 h):10 h dark daily lighting schedule. Experimental procedure was reviewed and approved by the ethical committee at the University of British Columbia.

Immature Sprague–Dawley rats were injected (i.p.) with 4 (control), 10, 20 or 40 (superovulation) IU pregnant mares’ serum gonadotrophin (PMSG; Equinex, Ayerst, Montreal, PQ) in 0.2 ml saline at 09:00 h at day 28 and mated overnight 60 h after the PMSG injection. A single injection of 4 IU PMSG in the immature rats created a normal pregnancy and thus served as the control (Nuti et al., 1975; Miller and Armstrong, 1981; Katagiri et al., 1996). A group of immature rats that had been induced to superovulate were implanted, s.c. on the back, with an Alzet osmotic pump (Model 1003D, Alza, Palo Alto, CA) at 10:00 h on day 1 (day of vaginal plug). Rats were infused (s.c.) with 1 mg anti-IGF-I antibody ml $^{-1}$ for 48 h at an infusion rate of 1 µl h$^{-1}$.

The effect of oestrogen on electrolyte composition of uterine luminal fluid was studied by injecting (i.p.) immature rats with 4 IU PMSG in 0.2 ml saline at 09:00 h at day 28, followed by daily injections (s.c.) with 0.1, 0.5, 1.0 or 5.0 mg oestradiol (Sigma, St Louis, MO) prepared in 0.1 ml sesame oil at 10:00 h from day 0 (day of oestrus) to day 2 of pregnancy. A group of rats given daily 5.0 mg oestradiol injections was infused with anti-IGF-I antibody as above.

Adult female Sprague–Dawley rats (340–360 g body mass) were mated overnight at oestrus and infused with human recombinant (hr)-IGF-I (Sigma) from day 1 (day of vaginal plug) to day 3 of pregnancy as described by Katagiri et al. (1996). Briefly, rats were ovarioectomized unilaterally on the right, via an incision made on the median line, between 10:00 h and 11:00 h on day 1 of pregnancy. An Alzet osmotic pump (Model 1003D) was filled with 100 µl of 10 mmol h $^{-1}$ IGF-I $1^{-1}$ and the distal end of the delivery tube of the pump was introduced into the right ovarian artery proximal to the uterine artery branch. The incision in the abdominal wall and skin was sutured, leaving the pump in the abdominal cavity. Infusion was for 48 h at an infusion rate of 1 µl h$^{-1}$. The left ovary and artery were left intact for the control. This IGF-I infusion has been shown to increase uterine IGF-I action to the same extent as that found after superovulation (Katagiri et al., 1996). The vehicle alone was infused into the control rats. Some adult rats were unilaterally ovarioectomized on day 1 but not infused (non-infusion group).

Five rats were used in all groups except for the oestradiol treatment groups, where three rats were used.

**Collection of the uterine luminal fluids**

All the rats were killed at 11:00 h on day 3 of pregnancy and the uterine horns removed. Uterine luminal fluid was collected by flushing the uterine lumen with degassed 0.3 mol mannitol $1^{-1}$ solution (0.25 ml per uterine horn), within 5 min of being killed. The uterine flushed were kept away from air contact to avoid changes in free CO$_2$ content. The uterine flushed were centrifuged at 3000 g for 10 min to remove cell debris. Uterine flushed from the left and right uterine horns in the same animals, injected with PMSG or oestradiol, were combined. Anion content in each supernatant was immediately determined, while an aliquot of each supernatant was saved and frozen at −70°C for the cation assay.

**Determination of electrolyte composition**

Cl$^{-}$ content was determined by the coulometric–amperometric method (Dietz and Bond, 1982). HPO$_4^{2-}$ and HCO$_3^{-}$ contents were determined, as total inorganic phosphorus and total CO$_2$ respectively, by using Kodak Ektachem Clinical Chemistry Slides (PHOS and ECO$_2$, Kodak, Eastman Kodak, Rochester, NY). Frozen supernatants of uterine luminal fluids were thawed, and 15 mmol LaCl$_3$ $1^{-1}$, 4 mmol CsCl $1^{-1}$, and 100 mmol HCl $1^{-1}$ were added. Na$^{+}$, K$^{+}$, Ca$^{2+}$ and Mg$^{2+}$ contents were determined by atomic absorption photospectroscopy (Sanui, 1971; Sanui and Rubin, 1982).

**Statistical analysis**

Total cation contents of uterine luminal flushed were compared by ANOVA followed by Tukey’s test using the computer software SYSTAT (SYSTAT, Inc., Evanston, IL).

**Results**

The concentrations of each electrolyte are presented as a percentage of the total amount of cations or anions (Figs 1–3). In the cations, the percentage of Na$^{+}$ in the superovulation group decreased by 26% and that of K$^{+}$ increased 27%, as compared with those of the control group (Fig. 1). In anions, the percentage of Cl$^{-}$ decreased by 15% and that of HCO$_3^{-}$ increased by 16%. Compositions of cations and anions in the other PMSG groups were similar to those of the non-infusion group (Figs 1 and 3). As a result, the Na$^{+}$:K$^{+}$ ratio decreased from 6.0:1 (control) to 1.3:1 (superovulation) and the Cl$^{-}$:HCO$_3^{-}$ ratio from 3.6:1 to 1.6:1. Oestradiol treatment in 4 IU PMSG-treated immature rats altered the composition of cations and anions in a dose-dependent manner (Fig. 2). As oestradiol dose increased, the percentages of Na$^{+}$ and Cl$^{-}$ decreased by > 20% and those of K$^{+}$ and HCO$_3^{-}$ increased to the same extent. Anti-IGF-I antibody infusion restored the alterations in cations, but not anions, in the superovulation and oestradiol treatment (1.0 and 5.0 µg) groups to the control amounts (Figs 1 and 2). IGF-I infusion altered the electrolyte composition of the uterine luminal fluid in the infused horns but did not change that of the control horns compared with
that of the non-infusion group (Fig. 3). The alterations in electrolyte compositions of both cations and anions in the infused horn were compatible with those observed in the superovulated or oestradiol-treated rats (Figs 1 and 2). Unilateral ovariectomy or vehicle infusion had no effect on the electrolyte composition and total cation content in the infused and control horns (Fig. 3). Total cation content in uterine luminal flushes of the superovulation and oestradiol treatment (1.0 and 5.0 µg) groups increased by more than twofold compared with that of the respective control group (P < 0.01, Table 1). IGF-I infusion in adult rats and anti-IGF-I antibody infusion in the superovulated or oestradiol treated immature rats had no effect on total cation content in the uterine luminal flushes (Table 1). Ca²⁺, Mg²⁺ and HPO₄²⁻ contents were constant throughout these experiments.

Discussion

The present study provided evidence that uterine growth factors may be involved in the regulation of the uterine electrolyte environment, and suggested that hyperoestrogenaemia caused by superovulation may alter the uterine electrolyte environment, at least in part, through increased IGF-I action. Although some observations were made under a pathophysiological condition, namely superovulation, our study suggests strongly the presence of an endocrine or paracrine regulation on the uterine electrolyte environment during preimplantation embryonic development.

Recent evidence suggests that ovarian steroid hormones exert many of their actions through growth factors and cytokines in the uterus. IGF-I is one of these growth factors
and its synthesis is primarily regulated by oestrogen in the uterus (Murphy et al., 1987; Murphy and Ghahary, 1990). In superovulated immature rats, PMSG injected to induce superovulation causes hyperoestrogenaemia that in turn increases IGF-I action in the uterus (Miller and Armstrong, 1981; Katagiri et al., 1996). The enhanced IGF-I action caused by hyperoestrogenaemia appears to be a mechanism by which superovulation alters the electrolyte composition of uterine luminal fluid. IGF-I infusion altered the electrolyte composition, as is observed after superovulation and oestradiol (1 and 5 μg) treatment, only in the infused horns. Alterations in cation composition after superovulation and oestradiol (1 and 5 μg) treatment were restored by anti-IGF-I antibody infusion to control concentrations, suggesting that exposure to high concentrations of IGF-I causes changes in cation composition. In contrast, the role for IGF-I in the regulation of anion composition is less clear. Although IGF-I infusion mimicked the alterations in anion composition caused by superovulation, anti-IGF-I antibody failed to restore these alterations in anion composition. This, however, does not rule out a role for IGF-I in regulating concentrations of anions in uterine luminal fluid. Alterations in the anion composition of uterine luminal fluid may be regulated by multiple factors including IGF-I. Therefore, inhibition of IGF-I action alone may not restore the altered anion composition, caused by the superovulatory treatment. This is in direct contrast to the regulation of cation composition, in which IGF-I appears to play a major regulatory role.

It is unclear how IGF-I causes alterations in the electrolyte composition of uterine luminal fluid. A possible explanation is that disruption of the endometrial epithelial cells may be responsible for the increase in the K⁺:Na⁺ ratio, since intracellular fluid has a greater K⁺:Na⁺ ratio than extracellular fluid. This is supported by the presence of desquamated cellular debris in the uterine flushings from superovulated rats (Miller and Armstrong, 1981). However, disruption of the uterine luminal epithelial cells is unlikely to contribute significantly to the increase in the K⁺:Na⁺ ratio observed in the present study: first, because a visible amount of cellular debris was observed in some of the uterine luminal flushes of the superovulation and IGF-I infusion groups but the amount of cellular debris was considerably less in the IGF-I group than that observed in the superovulation group, while comparable

![Fig. 3. The effect of insulin-like growth factor I (IGF-I) infusion on the electrolyte composition of uterine luminal fluid. Adult rats (n = 5) were mated at oestrus, infused with human recombinant insulin-like growth factor I (IGF-I, 10 nmol l⁻¹, 1 μl h⁻¹) from day 1 to day 3 of pregnancy. Uterine luminal fluid was collected on day 3. The electrolyte composition is presented as the mean percentage of each component to the total (a) cations or (b) anions. (a) □ Na⁺; □ K⁺; □ Ca²⁺; □ Mg²⁺; (b) □ Cl⁻; □ HCO₃⁻; □ HPO₄²⁻.

*eInfusions were performed on the right uterine horn and the left horn was used as the control.
changes in Na\(^+\) and K\(^+\) concentrations were observed in the two groups, and second, because the concentrations of HPO\(_4^{2-}\) were constant throughout these experiments. Since intracellular fluid contains high concentrations of inorganic phosphate, disruption of cells will result in an increase in HPO\(_4^{2-}\) concentrations, which was not observed in this study. The mechanism by which IGF-I regulates uterine electrolyte environment remains to be determined.

Damage to the uterine luminal epithelium caused by flushing of the uterine luminal and consequent contamination of uterine luminal flushes by plasma and interstitial fluid has been described in mice (Martin, 1984; Milligan and Martin, 1984). It is not known whether the presumed contamination of uterine luminal flushes contributed to the observed alterations in the electrolyte composition in the present study. The larger size of the rat uterus compared with the mouse uterus may limit the damage to the uterine luminal epithelium caused by uterine flushing. The previous study suggests that the degree of contamination of uterine flushes, caused by flushing of the uterine lumen, depends on the degree of uterine closure (Milligan and Martin, 1984). Uterine closure is not yet apparent in the rat uterus on day 3 of pregnancy, the day of sample collection in the present study. Thus the presumed contamination caused by flushing of the uterine lumen may not be critical in the present study. However, the contamination of uterine flushes by plasma and interstitial fluid may be necessary.

Superovulation may also increase uterine luminal fluid volume. In general, the sum of the four cations that were examined in this study well represents total cation concentrations in body fluid and total anion concentrations are equivalent to those of cations. Since total electrolyte concentration in body fluid is closely maintained, an increase in total cation content in uterine luminal flushes by approximately twofold, observed in the present study in response to superovulation and oestradiol treatment, may be associated with a comparable increase in the volume of uterine luminal fluid. The increase in cation content and uterine wet mass of up to twofold observed after superovulation in immature rats (Miller and Armstrong, 1981) is consistent with the accumulation of fluid in the uterus and uterine lumen. In contrast, total cation content in the uterine luminal fluid of the IGF-I infusion and superovulation plus anti-IGF-I antibody groups was indistinguishable from that of the non-infusion group. These observations suggest that the presumed increase in the volume of uterine luminal fluid caused by superovulation is mediated by oestradiol. Oestradiol may regulate the fluid volume directly or, more likely, the oestradiol action is mediated by undetermined factors other than IGF-I.

The ratio of Na\(^+\) : K\(^+\) in the non-infusion and 4 IU PMSG control groups of the present study (5.2:1 and 6.0:1, respectively) is different from that observed in uterine flushes obtained on day 5 of pregnancy (1.4:1) (Setty et al., 1973). Differences in experimental design between the two studies, such as animal treatment or timing of sample collection, may affect the electrolyte composition. However, the unusually low Na\(^+\) : K\(^+\) ratio (1.4:1) in the previous study suggests that the difference in the method of uterine luminal fluid collection may be largely responsible for the difference in the ratio of the two cations. The previous experiment used deionized water (0.5 ml per horn), while the present study used isotonic solution (0.25 ml per horn). Use of a large volume of hypotonic solution may inevitably increase K\(^+\) content by causing cell disruption during uterine luminal fluid collection.

Alterations in the electrolyte composition observed in the present study are characterized by a decrease in Na\(^+\) : K\(^+\) and Cl\(^-\) : HCO\(_3^-\) ratios from 6.0:1 (control) to 1.3:1 (superovulation) and from 3.6:1 to 1.6:1, respectively, in the PMSG-treated immature rats. These alterations may have a significant effect on embryonic development. The influence of electrolyte environment on preimplantation embryonic development has been studied by using the in vitro culture system. High concentrations of K\(^+\) in culture media reduce the rate of blastocyst formation in mice (Wiley, 1984; Lawitts and Biggers, 1991). Substitution of either Na\(^+\) or Cl\(^-\) in the embryo culture media reduced the rate of blastocoele expansion (Manejwala et al., 1989). Low concentrations of NaCl in the culture medium allow glutamine, a preferred energy substrate for early preimplantation embryos, to impair embryonic development (Chatot et al., 1989; Lawitts and Biggers, 1992). Thus, the decrease in Na\(^+\) : K\(^+\) and Cl\(^-\) : HCO\(_3^-\) ratios appears to be detrimental to preimplantation embryonic development or at least blastocyst formation. This is consistent with the observation that uterine luminal fluid obtained from the superovulated rats or uterine luminal fluid from the uterus that was exposed high concentrations of IGF-I decreases the rate of blastocyst formation (Katagiri et al., 1996).

In summary, IGF-I may play a central role in the regulation of the uterine electrolyte environment, especially cations, during preimplantation embryonic development. Superovulatory or oestradiol treatment may alter the electrolyte composition of uterine luminal fluid by increasing IGF-I action in the uterus. The changes in the electrolyte composition of uterine luminal fluid may partially explain the detrimental effect of uterine luminal fluid on embryonic development after superovulation. Further studies are needed to provide better understanding of the mechanisms by which oestradiol and IGF-I regulate the electrolyte environment and to elucidate their physiological significance. For example, the present study examined the effect of oestradiol in PMSG-primed immature rats in order to understand the effect of hyperoestrogenaemia in an immature rat superovulation model. Although the normality of pregnancies in PMSG-primed immature rats has been established (Nuti et al., 1975), confirmation of our findings that includes the effect of oestradiol on electrolyte composition by using non-gonadotrophin primed pregnant rats may be necessary before our findings can be generalized.
