Effect of adenylyl cyclase activation on intracellular and extracellular cAMP and cGMP in preimplantation cattle blastocysts

M. Grealy* and J. M. Sreenan

Animal Reproduction Department, Teagasc, Agriculture and Food Development Authority, Athenry, Co. Galway, Ireland

The effects of direct and indirect activation of adenylyl cyclase on the production of intracellular and extracellular cAMP and cGMP by 13- to 16-day-old cattle embryos were determined. Embryos were incubated for 2 h in a Krebs Ringer bicarbonate medium containing the phosphodiesterase inhibitor isobutyl-methylxanthine, to which stimulating agents forskolin (100 μmol l⁻¹), cholera toxin (2 μg ml⁻¹), or both were added. Total (intracellular and extracellular) basal cAMP and cGMP concentrations ranged from 6.65 ± 0.895 to 3.4 ± 0.708 fmol μg⁻¹ protein in 13-day-old embryos and from 4.05 ± 1.151 to 0.19 ± 0.041 fmol μg⁻¹ protein in 16-day-old embryos. Forskolin induced an increase (P < 0.001) in cAMP that ranged from 5.4-fold on day 13 to 2.7-fold on day 16, whereas cholera toxin induced an increase (P < 0.001) that ranged from 30-fold at day 13 to 21-fold at day 16, similar to the effect of forskolin and cholera toxin combined. Individually, forskolin and cholera toxin had no effect on cGMP concentrations, but together they induced an increase (P < 0.05). cAMP (P < 0.01) and cGMP (P < 0.001) concentrations decreased with embryo age from day 13 to day 16 for all treatments; the decrease was greater for cGMP than cAMP (5–24-fold versus 1.6–3.3-fold, respectively). It is concluded that inducible adenylyl cyclase is present in 13- to 16-day-old cattle embryos and that the embryos secrete cAMP and cGMP into the incubation medium. In addition, basal and inducible concentrations of cAMP and cGMP decrease with embryo age from day 13 to day 16. These observations indicate that cAMP and cGMP may have a role in the rapid embryonic cell proliferation that occurs at this time or in signalling to the endometrium.

Introduction

cAMP and cGMP are present in, and secreted by, 14- to 16-day-old cattle blastocysts during in vitro culture (Grealy et al., 1997). In adult cells, cAMP and cGMP are involved in cell cycle control, differentiation and cell proliferation (Boyon and Whitfield, 1983; Dumont et al., 1989; Christensen et al., 1996; Garcia-Ocana et al., 1996; Sarkar et al., 1997), and they may have similar roles in cell proliferation and differentiation during preimplantation embryo development.

Many hormones, neurotransmitters and other 'first messengers' act by controlling cAMP concentrations. This control is achieved by altering the activity of adenylyl cyclase, the enzyme that synthesizes cAMP. Binding of the first messenger to an appropriate receptor causes activation of the G protein Gs, which in turn stimulates adenylyl cyclase (Sunahara et al., 1996), thereby increasing cellular cAMP concentrations. Adenylyl cyclase may be activated directly by forskolin, which reversibly binds to the catalytic subunit (Seamon and Dalry, 1981), whereas the G protein may be activated directly by cholera toxin, which catalyses the ADP ribosylation of the α subunit of the Gs regulatory protein (Fishman, 1990). cAMP exerts its effects in the cell by binding to, and activating, its specific protein kinase, cAMP-dependent protein kinase (PKA), which in turn, activates or inhibits other proteins in the cell by phosphorylation.

cGMP is formed after activation of guanylyl cyclases and activates or inhibits several target proteins in the cell. The effects include activation of cGMP-dependent protein kinase (PKG), regulation of ion channels, and activation or inhibition of cAMP phosphodiesterases (PDE) which break down cAMP in the cell (Goy, 1991). In this way, cGMP interacts with the cAMP pathway.

Both cAMP and cGMP are exported from mammalian cells (for reviews see Barber and Butcher, 1983; Hamet and Tremblay, 1991). Although the physiological functions of extracellular cAMP or cGMP are not fully resolved, the egress of these cyclic nucleotides may be a means, in addition to PDE, of terminating their action as intracellular signal transduction agents. However, extracellular cAMP and cGMP may also participate in signalling, either by binding to cell surface receptors or by being degraded to adenosine or guanosine, which then act as agonists at purinergic receptors. In kidney cells, extracellular cAMP stimulates, and cGMP inhibits, sodium chloride absorption in the medullary thick ascending limb (Amlal et al., 1996). Cattle blastocysts...
secrete cAMP and cGMP during culture in vitro (Grealy et al., 1997), but the function of these secreted cyclic nucleotides in cattle embryos has not been established.

The adenylyl cyclase present in bovine and mouse oocytes may be atypical because it is insensitive to cholera toxin but responds to forskolin stimulation (Manejwala et al., 1986; Bilodeau et al., 1993). This is in contrast to the adenylyl cyclases of adult cells, which respond both to cholera toxin and forskolin (Sunahara et al., 1996). In mouse embryos, sensitivity to cholera toxin increases from the eight-cell to the blastocyst stage (Manejwala et al., 1986). There is no information on the nature or activation of adenylyl cyclase in cattle embryos, although changes in sensitivity to stimulation may be important in the control of development.

The aims of this study were as follows: (i) to establish dose–response effects of the PDE inhibitor isobutyl-methylxanthine (IBMX), the direct adenylyl cyclase activator forskolin, and the indirect adenylyl cyclase activator cholera toxin on cAMP and cGMP concentrations in 14- or 15-day-old cattle embryo; (ii) on the basis of the results from the dose–response investigations, to investigate the effects of activation of adenylyl cyclase, either directly or indirectly, on intra- and extracellular cAMP and cGMP concentrations in 13- to 16-day-old cattle embryos; and (iii) to examine whether sensitivity to adenylyl cyclase activators changes from day 13 to day 16, which is the crucial period for embryo–maternal signalling and embryo survival.

### Materials and Methods

#### Embryo recovery

Preimplantation embryos (n = 135) were recovered from 18-month-old Hereford-cross heifers (n = 32) as described by Grealy et al. (1997). Briefly, heifers were superovulated with 1500 IU PMSG (Folligon; Intervet, Cambridge) and luteolysis was induced with 500 µg cloprostenol (Estrumate; Coopers Animal Health, Berkhamsted) 48 h later. Artificial insemination was carried out at 6 h and 18 h after the onset of estrus. Embryo recovery was carried out during mid-ventral laparotomy performed under licence in accordance with the European Community Directive, 86-609-EC. Thiopentone sodium (5 g, i.v.; Rhone Merieux, Harlow) was used as the initial anaesthetic followed by closed circuit anaesthesia with halothane (May and Baker, Dagenham) and oxygen. Hatched elongated blastocysts were flushed from the uterus on days 13, 14, 15 and 16 (day 0 = day of first observation of standing oestrus). The composition of the collection medium was 0.1% (w/v) polyvinyl-alcohol, 139 mmol NaCl l⁻¹, 2.7 mmol KCl l⁻¹, 0.89 mmol CaCl₂, 2H₂O l⁻¹, 1.47 mmol KH₂PO₄ l⁻¹, 0.49 mmol MgCl₂, 6H₂O l⁻¹, 7.46 mmol Na₂HPO₄·2H₂O l⁻¹, 1 mmol glucose l⁻¹ and 0.5 mmol pyruvic acid (sodium salt) l⁻¹, pH 7.3. Embryo recovery was carried out between 09:00 h and 14:00 h on each day. After recovery, embryos were washed three times in sterile collection medium at 35°C and graded for apparent viability on a scale of 1 (excellent) to 3 (degenerate) on the basis of morphology and expected developmental stage for age according to Betteridge et al. (1980) and Grealy et al. (1996). Only grade 1 and 2 embryos were included in the study. Embryos occasionally fragmented during the recovery procedure, but when fragments corresponded to the above criteria with regard to width and granularity they were included in the study.

#### Embryo incubation and storage

Embryos or embryo fragments were incubated individually in 1 ml of a Krebs Ringer bicarbonate medium (KRB) in four-well plates (Nunc, Roskilde) in a humidified atmosphere of 5% CO₂ in air at 38.5°C for 2 h. The composition of the incubation medium was 108 mmol NaCl l⁻¹, 4.78 mmol KCl l⁻¹, 1.71 mmol CaCl₂·2H₂O l⁻¹, 1.19 mmol KH₂PO₄ l⁻¹, 1.19 mmol MgSO₄·7H₂O l⁻¹, 25 mmol NaHCO₃ l⁻¹, 1 mmol glucose l⁻¹, 0.5 mmol pyruvic acid (sodium salt) l⁻¹ and 0.1% (w/v) polyvinyl-alcohol, pH 7.4 when gassed with CO₂.

For determination of dose–response relationships, the PDE inhibitor IBMX (0.1–100 µmol l⁻¹), the direct activator of adenylyl cyclase forskolin (1–100 µmol l⁻¹) and the indirect activator of adenylyl cyclase cholera toxin (0.2–20 µg ml⁻¹) were used. Doses of IBMX, forskolin and cholera toxin were within the range used in studies on cattle oocytes (Bilodeau et al., 1993) and mouse embryos (Manejwala et al., 1986). On the basis of the results from the dose–response study, 13- to 16-day-old cattle embryos were treated with 100 µmol forskolin l⁻¹, 2 µg cholera toxin ml⁻¹, or a combination of 100 µmol forskolin l⁻¹ and 2 µg cholera toxin ml⁻¹. IBMX was dissolved in 1 mol NaOH l⁻¹ and neutralized with 0.1 mol HCl l⁻¹ to give a 50 mmol l⁻¹ stock. This was dissolved in KRB to give the final concentration. Forskolin was dissolved in dimethyl sulfoxide (DMSO) to give a 50 mmol l⁻¹ stock and cholera toxin was dissolved in distilled H₂O to give a 1 mg ml⁻¹ stock. These stock solutions were diluted in KRB and IBMX to give the final concentrations. The preparations of IBMX, forskolin, cholera toxin and DMSO were obtained from Sigma (Poole).

After incubation, embryos were washed three times in collection medium and once in glucose-free collection medium to avoid interference with the protein assay, and were transferred to 200 µl ice-cold 95% ethanol (Merck, Darmstadt) in 1.5 ml conical plastic tubes (Safe-twist, Eppendorf, Hamburg) and stored in liquid nitrogen. Samples of the final wash, of similar volume to the medium in which the embryos were transferred, were also stored frozen in 200 µl 95% ethanol for use as assay blanks.

At the end of each 2 h incubation, a 200 µl sample of incubation medium was taken for estimation of cyclic nucleotides. This was also transferred to 200 µl 95% ethanol and stored as described for the embryo samples.

#### Assays for cAMP, cGMP and protein

Each embryo sample (n = 135) was assayed for cAMP, cGMP and protein. The assays were carried out according to Grealy et al. (1997). Briefly, embryos were thawed, sonicated and centrifuged. The supernatants were dried down and assayed for cAMP and cGMP by acetylated radioimmunoassay (28).
New England Nuclear, Du Pont, Stevenage). The protein content of the pellets was measured by the Pierce Micro BCA protein assay (Pierce and Warriner Ltd, Chester). Results are expressed as fmol µg⁻¹ protein ± SEM. The intra- and interassay coefficients of variation (CV) were 7.5 and 8.9% for cAMP, 5.3 and 9.5% for cGMP, and 3.7 and 6.1% for protein, respectively.

cAMP and cGMP concentrations in the embryos (intracellular) and in the incubation medium (extracellular) were measured as per microgram embryonic protein to eliminate variation due to the difference in the size of embryos recovered on a given day. Concentrations of cAMP and cGMP in the incubation medium were corrected for volume and then divided by embryo protein content. Total cAMP and cGMP were estimated as intracellular cAMP + extracellular cAMP and intracellular cGMP + extracellular cGMP.

**Statistical analyses**

The cAMP and cGMP data, calculated as per μg protein, were compared by analysis of variance followed by Duncan's multiple-range test, where appropriate (Proc GLM; SAS, 1988).

**Results**

**Dose-response relationships for IBMX**

IBMX elicited a dose-dependent increase in total cAMP (P < 0.001) and cGMP (P < 0.01) concentrations. Intracellular cAMP and extracellular cGMP concentrations were highest at 10 mmol IBMX L⁻¹, whereas extracellular cAMP and
in intracellular cGMP concentrations reached a maximum at 1 mmol IBMX l⁻¹ and there was no further increase at 10 mmol l⁻¹. IBMX at 0.1 mmol l⁻¹ did not elicit an increase in the concentration of cAMP or cGMP (Fig. 1a,b).

**Dose–response relationships for forskolin**

Forskolin elicited a dose-dependent increase in total cAMP (P < 0.001), but had no significant effect on cGMP concentrations. Intracellular cAMP concentrations were highest at 100 μmol forskolin l⁻¹, while the increase in extracellular cAMP was smaller and was maximal at 10 μmol l⁻¹ and there was no further increase at 100 μmol l⁻¹ (Fig. 1c,d).

**Dose–response relationships for cholera toxin**

Cholera toxin elicited a large increase in total cAMP concentrations (P < 0.001) at all concentrations examined. The intracellular cAMP response was maximal at 0.2 μg ml⁻¹ and there was a smaller response at the highest concentration (20 μg ml⁻¹). Extracellular concentrations of cAMP were highest at 2 μg cholera toxin ml⁻¹ and also decreased at the highest concentration. Cholera toxin did not affect intracellular cGMP concentrations, but extracellular concentrations increased at 20 μg ml⁻¹ (P < 0.05; Fig. 1e,f). On the basis of these results, IBMX (1 mmol l⁻¹) was included in all subsequent treatments, and forskolin and cholera toxin were used at 100 μmol l⁻¹ and 2 μg ml⁻¹, respectively, to avoid the non-specific effects observed at the higher concentrations.

**Overall treatment effects in 13- to 16-day-old embryos**

Overall analysis of variance, in which all treatments were included, was conducted on the data. The effects of embryo age across treatments and of treatments over all days examined are summarized (Tables 1 and 2, respectively). The analysis of variance showed that intra- and extracellular cAMP concentrations were increased by treatment with forskolin, cholera toxin, and forskolin and cholera toxin (P < 0.001; Table 2). Intracellular cAMP concentrations decreased with embryo age from day 13 to day 16 inclusive (P < 0.001; Table 1) and there was a day × treatment interaction (P < 0.05). Extracellular cAMP tended to decrease with embryo age, but this decrease was not significant (P = 0.074; Table 1). Intra- and extracellular cGMP decreased with embryo age (P < 0.001; Table 1), but only intracellular cGMP was significantly increased by treatment with forskolin and cholera toxin (P < 0.01; Table 2) and there was no day × treatment interaction.

**Effect of forskolin on 13- to 16-day-old embryos**

Forskolin (100 μmol l⁻¹) elicited a significant increase in intra- and extracellular cAMP concentrations compared with IBMX controls on days 13, 14, 15 and 16 (P < 0.001; Fig. 2). There was also a decrease in intra- and extracellular cAMP concentrations with day (P < 0.001) and a day × treatment interaction (P < 0.001); the increase in cAMP concentrations elicited by forskolin was lower at days 15 and 16 than at days 13 and 14. Intra- and extracellular cGMP concentrations decreased with day (P < 0.001), but there was no effect of forskolin treatment on cGMP concentrations.

In the IBMX controls, there was no significant change in extracellular cAMP with day, but intracellular cAMP and cGMP (P < 0.01) and extracellular cGMP (P < 0.001) decreased with day.

**Effect of cholera toxin on 13- to 16-day-old embryos**

Cholera toxin (2 μg ml⁻¹) elicited a significant increase (P < 0.001) in intra- and extracellular cAMP concentrations

compared with IBMX controls on days 13, 14, 15 and 16 (Fig. 2). Intra- and extracellular cAMP concentrations decreased with day \( (P < 0.01) \) and there was a day \( \times \) treatment interaction \( (P < 0.01) \). Intra- and extracellular cGMP concentrations decreased with day \( (P < 0.01) \) but there was no effect of cholera toxin on cGMP concentrations. Cholera toxin (2 \( \mu \text{g ml}^{-1} \)) elicited higher intra- and extracellular cAMP concentrations than forskolin \( (P < 0.001) \).

**Effect of combined treatment with forskolin and cholera toxin in 13- to 16-day-old embryos**

Combined treatment with forskolin (100 \( \mu \text{mol l}^{-1} \)) and cholera toxin (2 \( \mu \text{g ml}^{-1} \)) elicited a significant increase in intra- and extracellular cAMP concentrations compared with IBMX controls on days 13, 14, 15 and 16 \( (P < 0.001; \text{Fig. 2}) \). Intracellular cAMP concentrations also decreased with day \( (P < 0.05) \) from day 13 to day 16 and there was a day \( \times \) treatment interaction \( (P < 0.05) \). Intra- and extracellular cGMP concentrations decreased with day \( (P < 0.001) \). Intracellular cAMP concentrations were increased \( (P < 0.005) \), whereas extracellular cGMP concentrations were unaffected by combined treatment with forskolin and cholera toxin.

Forskolin and cholera toxin in combination elicited higher concentrations of intra- and extracellular cAMP \( (P < 0.001) \) and cGMP \( (P < 0.05) \) than forskolin alone. There was no significant difference between total intra- and extracellular cAMP concentrations elicited by forskolin and cholera toxin together and cholera toxin alone. However, forskolin and cholera toxin in combination elicited higher concentrations of intracellular cGMP than cholera toxin alone.

The overall effect of the treatments was demonstrated by examining total cAMP or cGMP concentrations \( (\text{Fig. 2e,f}) \). Total cAMP concentrations in the IBMX controls showed a small decrease from day 13 to day 16 (1.6-fold; \( P < 0.05) \).
Total cAMP concentrations were increased by forskolin (P < 0.001) and decreased steadily with day from day 13 to day 16 (3.3-fold; P < 0.001). The increase in total cAMP concentrations elicited by cholera toxin (P < 0.001) was much larger than that elicited by forskolin, and also decreased between day 13 and day 16 (2.4-fold; P < 0.05). After combined treatment with forskolin and cholera toxin the increase in total cAMP concentrations was similar to that elicited by cholera toxin alone. Concentrations were 1.7-fold lower in 16-day-old embryos than in 13-day-old embryos (P < 0.05).

Total cGMP concentrations were not affected by any of the treatments. There was a marked decrease in cGMP concentrations between day 13 and day 16, which was observed across all treatments and ranged from a fivefold decrease after treatment with cholera toxin (P < 0.05) to a 23-fold decrease after forskolin (P < 0.001).

**Discussion**

The results of the present study indicate that adenylly cyclase is present in 13- to 16-day-old cattle embryos and is capable of activation, directly and indirectly. There is a significant effect of embryo age on cGMP and cAMP, and both basal and activated concentrations decrease significantly from day 13 to day 16.

On the basis of the results of the dose–response study, 1 mmol IBMX L−1 was used in the subsequent experiments. The increase in cAMP and cGMP accumulation in cattle embryos after IBMX treatment is most likely the result of a decrease in the breakdown of cAMP and cGMP due to the effect of IBMX on phosphodiesterase activity, rather than to increased formation of these cyclic nucleotides. Although 10 mmol IBMX L−1 increased cAMP and cGMP accumulation, this amount was not used, since at such concentrations IBMX acts as an adenosine receptor antagonist (Fredholm et al., 1994). A concentration of 1 mmol IBMX L−1 effectively prevented cyclic nucleotide hydrolysis.

In the dose–response study, 100 μmol forskolin L−1 was the most effective concentration and this was used in subsequent experiments. This concentration of forskolin was effective in activating adenylcyclase in mouse and cattle oocytes (Schultz et al., 1983; Bilodeau et al., 1993). In the present study, the increase in total cAMP concentrations in cattle embryos elicited by forskolin ranged from 5.5-fold at day 13 to 2.7-fold at day 16. This is lower than the 25-fold increase in zona-free cattle oocytes reported by Bilodeau et al. (1993) who used the same concentration of forskolin, but it is within the range reported by Manejwala et al. (1986) who used 100 μmol L−1 for mouse oocytes and 25 μmol L−1 for preimplantation mouse embryos. Therefore, it appears that the adenyl cyclase in 13- to 16-day-old cattle embryos is less responsive to forskolin than that present in cattle oocytes.

The large increase in cAMP concentrations induced by cholera toxin in cattle embryos is in contrast to mouse and cattle oocytes in which cholera toxin is a much less effective activator than forskolin (Manejwala et al., 1986; Bilodeau et al., 1993), but is consistent with mouse blastocysts in which cholera toxin is more effective than forskolin. However, in mouse blastocysts, cholera toxin induces only a 12-fold increase in cAMP over IBMX controls compared with an increase of 20- to 25-fold in the present study.

The increase in cGMP concentrations elicited by cholera toxin at 20 μg ml−1 was unexpected, since cholera toxin is a specific activator of adenylly cyclase. Although there are no similar reports for embryos, Ledoux et al. (1997) reported increased cGMP concentrations in renal cells after treatment with cholera toxin (20 μg ml−1). They proposed that the effect was due to modulation of cGMP production by PKA through an intermediary protein.

The increase in intra- and extracellular cAMP concentrations induced by combined treatment with forskolin and cholera toxin was similar to that elicited by cholera toxin alone, but greater than that elicited by forskolin alone. This lack of synergism of forskolin and cholera toxin is in contrast to the study of Manejwala et al. (1986) in mouse blastocysts in which a fivefold increase in cAMP concentrations was observed after combined treatment with forskolin and cholera toxin compared with cholera toxin alone. However, forskolin is relatively more potent and cholera toxin relatively less potent in mouse blastocysts compared with the cattle blastocysts used in the present study in which maximum stimulation of adenylly cyclase was achieved with 2 μg cholera toxin ml−1 and the addition of forskolin was unable to increase the response further. However, a small increase in intracellular cGMP concentrations compared with IBMX controls was observed after combined treatment with forskolin and cholera toxin, and this was not observed when either activator was administered separately. This increase may be attributed to a modulation of cGMP concentrations by PKA similar to that proposed by Ledoux et al. (1997) for renal cells after treatment with 20 μg cholera toxin ml−1.

A consistent finding in the results of the present study was the large decrease in cGMP concentrations in 16-day-old compared with 13- and 14-day-old embryos. An equally consistent but smaller decrease was observed for cAMP. Grealy et al. (1996) reported a marked increase in embryo size and protein content during this time. Since cGMP inhibits proliferation in vascular smooth muscle cells (Sarkar et al., 1997; Yu et al., 1997) and osteoblastic cells (Hagiwara et al., 1996), it is possible that the decrease in cGMP concentrations in 15- to 16-day-old embryos is a signal for proliferation within the embryo. Nitric oxide, which acts by increasing cGMP concentrations, is produced by preimplantation mouse embryos and is required for their development (Gouge et al., 1998). However, high concentrations of nitric oxide inhibit both embryo development in vitro and implantation in vivo in mice (Barroso et al., 1998). Therefore, it is possible that the decrease in cGMP concentrations during the days leading up to implantation in cattle embryos reflects a decrease in nitric oxide production by the embryo. In addition, whereas intracellular cAMP concentrations are consistently higher than extracellular concentrations across all treatments, the opposite is the case for cGMP. This indicates that cGMP has an important role as an extracellular messenger in addition to its intracellular role.

The present study augments the data on the export of cAMP and cGMP by cattle embryos (Grealy et al., 1997).
the present study, changes in intracellular cAMP and cGMP concentrations were reflected by changes in their extracellular concentrations. The roles of extracellular cAMP and cGMP have not been elucidated. One possibility is that they are degraded by a series of extracellular enzymes to adenosine and guanosine, which may, in turn, act as a signal via purinergic receptors either within the embryo or between the embryonic and maternal tissues. Purinergic receptors have been identified in bovine oviduct epithelial cells (Cox and Leese, 1995) and in mouse (Chan et al., 1997), rat (Dehpour et al., 1994) and guinea-pig (Haynes and Pennenfather, 1993; Piper and Hollingsworth, 1996) uterine epithelia, although there are no reports of their presence in embryos. Adenosine, acting via increased cAMP concentrations, inhibits proliferation in smooth muscle cells (Jonzon et al., 1985). Decreased cAMP concentrations may therefore stimulate proliferation.
