The conversion of [¹⁴C]arginine into [¹⁴C]citrulline as an indicator of nitric oxide synthesis was studied in uteri isolated from rats on different days of gestation, after labour and during dioestrus. Nitric oxide synthesis was present in uterine tissues isolated at each stage of gestation and also in tissues collected during dioestrus and after labour. Expression of neuronal nitric oxide synthase was not detectable at any of the stages studied. Endothelial nitric oxide synthase was present at all the stages studied, but there was a significant increase on day 13 of gestation and a decrease thereafter, with the lowest expression recorded on the day after labour. Inducible nitric oxide synthase expression in rat uteri increased substantially during pregnancy, with the highest expression on day 13 of gestation; expression decreased at term and after labour. The changes in expression of inducible nitric oxide synthase were coincident with the changes in nitric oxide synthase activity in uteri treated with aminoguanidine. Thus, these findings indicate that an increase in expression of inducible nitric oxide synthase in the uterus may be important for maintenance of uterine quiescence during pregnancy and its decrease near the time of labour could have an effect on the start of uterine contractility.

Introduction

Nitric oxide is an inorganic free radical gas that is well recognized as the principal mediator of several functions, including the relaxation of smooth muscles in a variety of tissues (Moncada et al., 1991).

Nitric oxide is generated from L-arginine by nitric oxide synthase. Multiple isoforms of this enzyme have been reported (Moncada and Higgs, 1993). Nerve fibres synthesizing nitric oxide have been demonstrated in the uteri of nonpregnant rats and mice by co-localization with NADPH diaphorase and by immunoreactivity using antibodies raised against pig and rat neuronal nitric oxide synthase and inducible nitric oxide synthase (Papka and McNeill, 1992; Grozdanovic et al., 1994; Suburo et al., 1995).

Nitric oxide regulates smooth muscle cell contractility and spontaneous contraction during the oestrous cycle, as well as distension of the uterus during pregnancy (Izumi and Garfield, 1995). The activity of nitric oxide synthase in maternal tissues increases early in pregnancy and an increased activity of nitric oxide synthase plays a role in adaptation of vascular and gastrointestinal muscle in guinea-pigs during this period (Weiner et al., 1994; Purcell et al., 1997). Nitric oxide has also been implicated in peripheral vasodilatation in pregnancy and in the control of blood flow in the fetoplacental circulation (Poston et al., 1995). Some studies have implicated a nitric oxide–cyclic guanosine monophosphate relaxation pathway as responsible for maintaining uterine quiescence during pregnancy in humans and rats (Izumi et al., 1993; Buhimischi et al., 1995). Other studies demonstrated an increase in expression of inducible nitric oxide synthase mRNA in rat uteri and a minor increase in expression of endothelial nitric oxide synthase and neuronal nitric oxide synthase mRNA during late pregnancy (Ali et al., 1997; Dong et al., 1998). Riemer et al. (1997) used immunohistochemistry to show that there is expression of inducible nitric oxide synthase and endothelial nitric oxide synthase in myometrium on days 17–18 of pregnancy and that expression decreased at term in rats in labour. However, the production of nitric oxide in early, mid- and late pregnancy was not compared in these studies, so it is not known when nitric oxide synthesis starts to increase.

The aim of the present study was to examine: (i) the production of nitric oxide in uteri from pregnant rats at early, mid- and late pregnancy and after labour; and (ii) differences in the expression of different isoforms of nitric oxide synthase at the same stages of pregnancy.

Materials and Methods

Drugs and chemicals

Aminoguanidine, N⁶-nitro-L-arginine methyl ester (L-NAME), N⁶-nitro-D-arginine methyl ester (D-NAME) and L-valine were purchased from Sigma Chemical Co (St Louis, MO). [¹⁴C]arginine was purchased from Amersham Corporation (Arlington Heights, IL). Dowex AG 50W-X8 cation exchange resin was obtained from Bio-Rad.
Laboratories (Alfatron, SRL, Buenos Aires). The western blotting reagents were obtained from Sigma and Bio-Rad Chemicals. The antibodies for western blotting were obtained from Transduction Laboratories (Lexington, KY). All other chemicals were analytical grade.

**Animals**

Time-mated pregnant rats of the Wistar strain (200–230 g body weight) were used. The rats were maintained on a 12 h light:12 h dark schedule. Animal chow and water were available ad libitum. Pregnant animals (n = 6 for each stage of pregnancy) were killed on different days of gestation (days 5, 13, 21 and 22) and 1 day after parturition. Spontaneous term labour typically occurred at night on day 22 of gestation (day 1: day on which a sperm plug was observed). Uterine tissue was also obtained from cyclic nonpregnant rats (n = 6) in dioestrus. All the animals were stunned by a blow on the neck. The uterus of each rat, containing both myometrium and endometrium, was removed immediately, cleaned of fat, placenta, fetuses, fetal membranes and blood vessels, and was rinsed thoroughly in cold Krebs’ ringer bicarbonate buffer (KRB) for determination of nitric oxide synthase activity or extracted for western analysis.

**Conversion of [14C]arginine into [14C]citrulline**

The release of nitric oxide from incubated uterine strips was measured using the modified method of Bredt and Snyder (1989), which measures the conversion of [14C]arginine into [14C]citrulline, as citrulline remains in the sample, whereas the equimolar amounts of nitric oxide produced are rapidly destroyed. Cross-sectional slices were cut from the centre of the uterus. The slices were incubated in a buffer that contained 20 mmol Hepes l−1, 10 μmol [14C]arginine l−1 (0.3 μCi) and 0.5 mmol NADPH l−1. Nitric oxide synthase inhibitors (L-NAME or aminoguanidine) were added at this stage when required. Valine (25 mmol l−1), which inhibits the conversion of L-arginine into L-citrulline by arginases by 25–40% in 0.25 mmol sucrose l−1, EDTA (1 mmol l−1), phenylmethyl sulphonyl fluoride (100 μg ml−1), aprotinin (10 μg ml−1), leupeptin (10 μg ml−1) and sorbent trypsin inhibitor (10 μg ml−1). After centrifugation at 7800 g for 10 min, the supernatants were collected and stored at −70°C until western blotting was performed. Each point represents pooled material from four animals. Seventy micrograms of protein were loaded in each lane. Positive control aliquots were also loaded. Membrane fraction of human endothelial cells was used for endothelial nitric oxide synthase, mouse macrophage lysate for inducible nitric oxide synthase and rat pituitary lysate for neuronal nitric oxide synthase (Transduction Laboratories, Lexington, KY). Samples were separated on a 7.5% (w/v) sodium dodecyl sulphate-polyacrylamide gel by electrophoresis and transferred to a nitrocellulose membrane (Pharmacia Biotech, Sweden). The blots were incubated with a rabbit antiserum for 2 h at room temperature for anti-endothelial nitric oxide synthase, anti-inducible nitric oxide synthase and anti-neuronal nitric oxide synthase antibodies. All the primary antibodies were used at a final dilution of 1:1000 in the blocking buffer. The blots were washed with wash buffer (10 mmol Tris l−1, 100 mmol NaCl l−1 and 0.1% (v/v) Tween-20, pH 7.5) followed by alkaline phosphatase-conjugated anti-rabbit IgG as the secondary antibody and were developed with 5-bromo-4-chloro-3-indolyl-phosphate toluidine Salt (BCIP) and nitroblue tetrazolium (NBT). Molecular weight markers were used to identify the protein bands. Photographs of the membranes were taken and they were densitometrically scanned and analysed using a Dekmate III scanner and Sigma Gel software package. The concentration of protein loaded in each lane was measured by the Bradford method (Bradford, 1976).

**Statistics**

Statistical significance was tested by Student–Newman–Keuls multiple comparison test for unequal replicates. The level of significance was P < 0.05.

**Results**

Conversion of [14C]arginine into [14C]citrulline

Nitric oxide synthase activity was present in uterine tissues from each stage of gestation that was examined and also in tissues taken during dioestrus and after labour. Nitric oxide synthase activity was at a maximum at day 13 of gestation and at a minimum at day 22 of gestation and after labour (Fig. 1). The effects of L-NAME (300 μmol l−1), a competitive inhibitor of all nitric oxide synthase isoforms, and D-NAME (300 μmol l−1), an inactive enantiomer, were investigated on days 5, 13 and 21 of pregnancy to determine whether citrulline production was related specifically to activity of nitric oxide synthases. L-NAME inhibited enzyme activity compared with control values on days 5, 13 and 21 of pregnancy to determine whether citrulline production was related specifically to activity of nitric oxide synthases. L-NAME inhibited enzyme activity compared with control values on days 5, 13 and 21 of pregnancy by 45, 67 and 59%, respectively (Fig. 2). D-NAME was unable to inhibit nitric oxide synthase activity. The effect of aminoguanidine (500 μmol l−1), a selective inhibitor of inducible nitric oxide synthase (Misko et al., 1993), on nitric oxide production was also investigated on...
uterine tissues from the different stages. Aminoguanidine decreased nitric oxide synthase activity significantly in samples of nonpregnant dioestrous uterus and uterus collected on days 5 and 13 of pregnancy (Fig. 3); the presence of inducible nitric oxide synthase was examined in light of the observation that aminoguanidine decreased nitric oxide production in these states.

**Immunodetection of nitric oxide synthase proteins**

Western blotting was used to determine the presence of different nitric oxide synthase enzymes, to measure the amount of nitric oxide synthase proteins present in the uterus and to determine whether the proteins changed in a manner that correlated with the changes in activity. Neuronal nitric oxide synthase was not detected in western blots of uterine extracts in any of the states studied (Fig. 4). The monoclonal antibody to endothelial nitric oxide synthase reacted with the appropriate band corresponding to the 140 kDa protein from the membrane fraction of human endothelial cells. A band at 140 kDa corresponding to the size of endothelial nitric oxide synthase was expressed at detectable levels in uteri from all the states studied (Fig. 5a). Densitometric analysis revealed that expression of endothelial nitric oxide synthase protein was high in nonpregnant dioestrous uterus and at day 13 of pregnancy, and that its expression was reduced in uteri collected at day 22 of pregnancy and after labour (Fig. 5b). The monoclonal antibody to inducible nitric oxide synthase reacted with the band corresponding to 130 kDa. Expression of inducible nitric oxide synthase was detectable in uteri from nonpregnant dioestrous rats and uteri collected at days 5, 13 and 21 of gestation (Fig. 6a). Inducible nitric oxide synthase expression was not detected at day 22 of pregnancy or in uteri collected after labour. Densitometric analysis showed that expression of inducible nitric oxide synthase is at a maximum at day 13 of gestation (Fig. 6b).

**Discussion**

The results of the present study demonstrate the presence of inducible nitric oxide synthase and endothelial nitric oxide synthase, and nitric oxide synthase activity in pregnant and nonpregnant rat uteri. Conversion of arginine to citrulline...
Nitric oxide synthesis and the expression of isoforms of nitric oxide synthase during early, mid- and late pregnancy and after labour were also studied. Nitric oxide synthesis was at a maximum at day 13 of pregnancy and at a minimum on day 22 of pregnancy and after labour. Nitric oxide production augmented in the second part of pregnancy and the values of nitric oxide synthesized during the first part of pregnancy were similar to those of nonpregnant dioestrous uteri. Other studies have shown that generation of nitric oxide is upregulated during pregnancy and downregulated during delivery and after labour (Dong et al., 1996; Riemer et al., 1997). Neuronal nitric oxide synthase was not detected during pregnancy in the present study, thus supporting the results of Dong et al. (1996) and Buhimschi et al. (1996). These authors reported that neuronal nitric oxide synthase was detectable in the uterus of prepubertal rats and in nonpregnant adult rats. Suburo et al. (1995) used histochemical and immunohistochemical methods to demonstrate the presence of neuronal nitric oxide synthase in uteri from cyclic rats during dioestrus and metoestrus. However, in the present study, neuronal nitric oxide synthase was not detected in uteri collected during dioestrus or after labour. It is possible that the sensitivity of the antibody used was not sufficient to detect this protein. The absence of neuronal nitric oxide synthase during pregnancy could be attributed to degenerating nerves in the uterus during this stage (Stjernquist and Sjöberg, 1994). Immunostaining with two antisera against neuronal nitric oxide synthase yielded the same results, being strictly confined to nerve fibres (Suburo et al., 1995).

The effects of aminoguanidine (a selective inhibitor of inducible nitric oxide synthase activity) on nitric oxide production were also investigated in the present study. Aminoguanidine significantly decreased nitric oxide synthase activity in nonpregnant dioestrous uterus and in uteri collected on days 5 and 13 of pregnancy. The decrease in nitric oxide synthase activity induced by aminoguanidine parallel the changes in inducible nitric oxide synthase expression in all the states studied. Densitometric analysis showed that expression of inducible nitric oxide synthase was at a maximum at day 13 of gestation, but an inducible nitric oxide synthase band was detected on days 5 and 21 of pregnancy and in dioestrous uteri. However, even if we have observed an important expression of inducible nitric oxide synthase in dioestrus, there was only a slight inhibition of nitric oxide synthase activity by aminoguanidine in this state. Therefore, there is probably not a direct relationship between expression of inducible nitric oxide synthase and its activity during dioestrus. Perhaps the lack of activation of the enzyme could be attributed to absence of some cofactors or the presence of inhibitors.

Expression of endothelial nitric oxide synthase was high in nonpregnant dioestrous uterus and at day 13 of pregnancy, but it was also present, although in lower quantity, in uteri collected at day 22 of pregnancy and after labour. There were lower pregnancy-associated changes in nitric oxide synthesis of Ca2+-dependent nitric oxide synthase activity after treatment with aminoguanidine than changes in total

was reduced by pre-incubation with L-NAME (a nitric oxide synthase inhibitor) but not by D-NAME (its inactive enantiomer). L-NAME inhibited enzyme activity by 45, 67 and 59% on days 5, 13 and 21, respectively. A high concentration of L-NAME (600 μmol l⁻¹) reduced the conversion of arginine to citrulline by about 90% in rat uteri (data not shown).
nitric oxide synthase activity, indicating that this isoform may not be principally responsible for the changes in nitric oxide synthesis observed during pregnancy. This finding supports those of Dong et al. (1996) and Natuzzi et al. (1993), in which there were no significant pregnancy-associated changes in Ca²⁺-dependent nitric oxide synthase activity (activity of constitutive enzymes). Progestrone can augment the expression of inducible nitric oxide synthase and endothelial nitric oxide synthase in nonpregnant rat uteri (D. Ogando, M. Farina, M. L. Ribeiro, S. Perez Martinez, M. Cell, V. Rettori and A. Franchi, unpublished). This finding and the fact that expression of endothelial nitric oxide synthase and inducible nitric oxide synthase and nitric oxide synthases are high when progesterone concentrations are also high during pregnancy may indicate that expression of inducible nitric oxide synthase may be regulated, at least partially, by progesterone. This conclusion is further supported by the study of Dong et al. (1996), in which the induction of preterm labour by the antiprogestosterone RU486 was associated with an important decrease in inducible nitric oxide synthase expression.

In summary, the presence of inducible nitric oxide synthase and endothelial nitric oxide synthase protein in rat uteri has been demonstrated by western blotting. Expression of inducible nitric oxide synthase is increased during mid-pregnancy and is undetectable at the last day of pregnancy and after labour. Changes in endothelial nitric oxide synthase content (an increase on day 13 of pregnancy and a later decrease) were also observed, but this isoform is present during all stages of pregnancy and after labour. Nitric oxide synthase activity in aminoguanidine-treated rat uteri is decreased compared with control values during pregnancy and does not change after labour. These observations, together with previous studies showing that the blockade of nitric oxide synthase or removal of nitric oxide prevented the spontaneous decrease in uterine motility (Franchi et al., 1994) and with the findings of Izumi et al. (1993) demonstrating an l-arginine–nitric oxide system in rat myometrium that has an important role inhibiting uterine contractility, indicate that an increase in expression of inducible nitric oxide synthase in the uterus may be important in the maintenance of uterine quiescence during pregnancy and that a decrease in its activity is coincident with the beginning of the uterine contractions that are necessary for labour.
