The fertility of dairy cows decreases during the summer and remains low during the cooler autumn although the animals are no longer under heat stress. The aim of this study was to characterize a delayed effect of summer heat stress on oocyte quality in the autumn and to improve oocyte quality by enhanced removal of follicles damaged during the previous summer. Lactating cows ($n = 16$) were subjected to heat stress during the summer. In autumn, ovarian follicles (3–7 mm in diameter) were aspirated by an ultrasound-guided procedure during four consecutive oestrous cycles. Follicles were aspirated from control cows on day 4 and from treated cows on days 4, 7, 11 and 15 of each oestrous cycle. All cows received PGF_{2α} and GnRH injections on days 19 and 21, respectively, and maintained cyclicity, as indicated by plasma progesterone concentrations. On day 4 of each cycle, the oocytes recovered were examined morphologically, matured and activated *in vitro*,

and cultured for 8 days. In cycle 1 (early October) both groups showed low percentages of grade 1 oocytes, cleavage, four- and eight-cell embryos, morulae and parthenogenetic blastocysts. Subsequently, the number of grade 1 oocytes increased earlier (cycle 2) in treated than in control cows (cycle 3; $P < 0.05$). The cleavage rate in the control group remained relatively low throughout (32–58%), whereas in the treated group it increased from 40% (cycle 1) to 75% (cycles 3 and 4; $P < 0.05$). The number at each stage of embryo development increased slightly but remained low throughout in the control group, whereas in the treated group significant ($P < 0.05$) increases of all stages were observed in cycles 3 and 4. The results show a delayed effect of summer heat stress on oocyte quality and embryo development in the autumn. Enhanced removal of the impaired cohort of follicles led to earlier emergence of healthy follicles and high quality oocytes in the autumn.

Introduction

Low fertility of dairy cattle during the summer in tropical, subtropical and temperate regions is a well-documented event. A less well-known fact is that during the autumn, although the weather is cooler and the cows are no longer subjected to thermal stress, the conception rate remains low (Ron *et al.*, 1984; Badinga *et al.*, 1985). Moreover, the mechanisms by which summer heat stress induces low fertility during the subsequent autumn are not clear.

The susceptibility of oocytes to short-term thermal stress has been documented in both *in vitro* and *in vivo* studies. Exposure of fertilized oocytes to increased temperatures had a deleterious effect on early embryonic development (Edwards and Hansen 1996, 1997; Rivera and Hansen, 2001). Exposing heifers to short-term, acute heat stress before artificial insemination increased the number of retarded and abnormal embryos (Putney *et al.*, 1988).

Seasonal studies have shown that quality of bovine oocytes and rate of embryo development deteriorate in the summer compared with the winter (Rocha *et al.*, 1998; Rutledge *et al.*, 1999), and that the lipid composition of oocyte membranes differs between the seasons (Zeron *et al.*, 2001). However, there have been no published reports of a delayed effect of heat stress on oocyte quality. Roth *et al.* (2000) showed that exposing cows to thermal stress during one oestrous cycle altered follicular dynamics and attenuated follicular dominance in the subsequent cycle. In another study, in which cows had been exposed to short-term acute heat stress, medium-sized and preovulatory follicles that had been in early stages of follicular development during the heat exposure showed reduced steroid production several weeks after heat stress had ended (Roth *et al.*, 2001). Thus, exposure of follicles to hyperthermia in the summer, during the early stages of development, may impair oocyte quality and subsequent embryo development during the autumn. Fertility data sets indicate that a period of about 2 months (equivalent to three or four oestrous cycles) is needed for low autumn fertility to

*Correspondence

be restored to the level prevailing in the winter (Ron *et al.*, 1984). We hypothesized that during the autumn, the normal growth and atresia of follicles within the follicular wave dynamics causes slow depletion of the cohort of heat-stress-impaired follicles from the ovaries. Thus, enhanced removal of the pool of impaired follicles should advance the growth of healthy follicles and improve autumn fertility. Enhanced removal could be achieved by transvaginal aspiration of all visible follicles using the ovum pick-up procedure (Pieterse *et al.*, 1988, 1991), which has induced the emergence of a new follicular wave within 1.5–2.0 days (Bergfelt *et al.*, 1994; Garcia and Salaheddine, 1998). Long-term repeated removal (twice a week) of all follicles > 2 mm in diameter increased the number of follicular waves in cattle (Boni *et al.*, 1997; Garcia and Salaheddine, 1998) without compromising the subsequent cyclicity of the donors (Pieterse *et al.*, 1991; Kruip *et al.*, 1994).

The aims of the present study were: (i) to examine a possible delayed effect of summer heat stress on oocyte quality and embryo development during the autumn; and (ii) to determine whether frequent follicular aspiration improved oocyte quality during the autumn.

Materials and Methods

Animals

The experiment was conducted during the autumn (October to November) in the experimental dairy herd of the Agricultural Research Organization in Bet Dagan, Israel; it involved 16 cyclic Holstein lactating cows that had been subjected to thermal stress during the previous summer (June to early October). During the experiment, the cows were fed a complete mixed ration containing 16.5% (w/v) protein, 1.7 Mcal kg⁻¹ dry matter and 32% (w/v) neutral detergent fibre. Artificial light was supplemented in the barn to obtain 18 h of light per 24 h, thereby minimizing potential effects of photoperiod. At the beginning of the experiment the cows were, on average, at day 90 after parturition and yielded 35 kg milk day⁻¹. Oestrus was synchronized using an intra-vaginal device containing progesterone (CIDR; Eazi Breed, Hamilton) and by i.m. injection of PGF_{2α} analogue (500 µg cloprostenol; Estrumate, Coopers, Berkhamsted). The synchronized cows were assigned randomly to control (*n* = 8) or treatment (*n* = 8) groups.

Air temperature and relative humidity data were obtained from the Central Meteorological Station located 3 km from the herd. The temperature humidity index (THI) was calculated according to Ingraham *et al.* (1974): $THI = DBT - (0.55 - 0.55 \times RH)(DBT - 58)$, where DBT is the dry bulb temperature and RH is the relative humidity. The average daily sums of THI values exceeding 72 ($THI > 72$), which is the level generally considered stressful for dairy cattle (Johnson, 1976), were provided by the Meteorological Services. Data on conception rates were obtained from the Israeli herd book. The local ethics committee approved the experiment.

Experimental protocol

During four consecutive oestrous cycles, all visible follicles (3–7 mm in diameter) were aspirated by the transvaginal follicular aspiration procedure (Pieterse *et al.*, 1988). Follicles were aspirated on day 4 of each oestrous cycle in the control group and on days 4, 7, 11 and 15 of each cycle in the treated group, which is of sufficient frequency to prevent the development of dominant follicles (Kruip *et al.*, 1994; Garcia and Salaheddine, 1998). Comparison between experimental groups was made on the basis of oocytes collected on day 4 of each of the four oestrous cycles, before establishment of follicular dominance (Ginther *et al.*, 1996). The same experienced veterinarian performed all follicular aspirations throughout the experiment. PGF_{2α} (500 µg cloprostenol) was injected i.m. on day 19 of each oestrous cycle to regress the corpora lutea and a dose of GnRH analogue (2.5 ml; Receptal; Hoechst, Wiesbaden) was injected i.m. on day 21 (day 0 of the subsequent oestrous cycle) in both groups to induce ovulation of the preovulatory follicle. A 6 day interval between the last aspiration (day 15) and GnRH injection was sufficient to allow development of a large, dominant, preovulatory follicle in the treated group (Kruip *et al.*, 1994). This experimental design enabled us to synchronize four consecutive oestrous cycles accurately while preserving a normal pattern of growth and regression of corpora lutea and induction of follicular phases, during which preovulatory follicles developed and ovulated in both groups. The follicular dynamics were monitored every 2 days during one representative cycle (cycle 2). Blood samples were collected on days 3, 11, 16, 19 and 20 of cycle 1 and on days 0, 2, 5, 8, 9, 15, 19 and 20 of cycle 2; the samples were centrifuged at 2000 g for 20 min and plasma was stored at –20°C until required.

Follicular aspiration and oocyte collection

Cows were sedated with 20 mg xylazine i.m. (Rompun 2%, Bayer, Bury St Edmunds) to simplify the manipulation of the cow and the ovary. Caudal epidural anaesthesia was induced with 5 ml of 2% (w/v) lidocaine to provide relaxation and analgesia to the rectovaginal region. Follicles were aspirated using an ultrasonic scanner (Pie Medical, Maastricht) and a 7.5 MHz vaginal sector transducer equipped with a needle guide attached to an 18-gauge needle that was connected to a suction pump, set at a flow rate of 25–30 ml min⁻¹. For each cow, in each session, follicular contents from all visible follicles 3–7 mm in diameter were collected into a single 50 ml tube, which contained 5 ml working medium: 10 mmol Hepes-TL solution l⁻¹ (Sigma, St Louis, MO) supplemented with antibiotics (5 µg gentamicin l⁻¹; Sigma), 0.2 mmol sodium pyruvate l⁻¹ (Sigma) and heparin (500 iu per 100 ml; Sigma) in 0.4% (w/v) BSA. The tubes containing the aspirated follicular contents were taken immediately to the nearby laboratory for collection of cumulus–oocyte complexes

(COCs). Recovered COCs were counted, examined morphologically and classified into four categories according to the number of layers of the cumulus surrounding the oocytes and their cytoplasmic consistency, as described elsewhere (De-Loos *et al.*, 1989; Reichenbach *et al.*, 1994): grade 1: spherical, symmetrical and intact oocytes of uniform size, colour and texture, surrounded entirely by three to five compact layers of cumulus cells; grade 2: incomplete COC, partially denuded; grade 3: expanded, denuded, partially degenerated cumulus; and grade 4: totally degenerated COC.

Oocyte maturation and parthenogenetic activation

Recovered COCs were washed three times with oocyte wash buffer (K-SIWB; Cook, Sydney) and transferred separately for each cow into four-well culture multi-dishes (Nunc, Roskilde) containing 500 µl maturation medium: TCM-199 (Sigma) supplemented with 25 mmol Hepes l⁻¹, supplemented with 0.2 mmol sodium pyruvate l⁻¹ (Sigma), 5 µl gentamicin l⁻¹ (Sigma), 10% (v/v) heat-inactivated fetal calf serum (FCS; Bio-Lab, Jerusalem,), 10 µg ovine LH ml⁻¹ (NIADDK-NIH-26, AFP5551B; Bethesda, MD), 1 µg FSH ml⁻¹ (NIADDK-NIH-20, AFP7028D; Bethesda, MD) and 1 µg oestradiol ml⁻¹, as described elsewhere (Leibfried and First, 1979; Zeron *et al.*, 2001). COCs were incubated for 24 h at 38.5°C in a humidified atmosphere of air containing 5% CO₂. After maturation, cultured oocytes were denuded fully of cumulus cells by pipetting and were activated with ionomycin (Sigma) followed by 6-dimethylaminopurine (Sigma), as described elsewhere (Loi *et al.*, 1998; Zeron *et al.*, 2001). Avoiding the embryo transfer approach in the present study enabled us to use the oocyte activation procedure, with the advantage that embryo development is examined irrespective of the involvement of sperm cells, thereby avoiding fertilization failure that might occur during IVF. In brief, matured oocytes were activated for 5 min in ionomycin medium: 10 ml TCM-199 supplemented with 25 mmol Hepes l⁻¹, 10% (v/v) heat-inactivated FCS, 0.2 mmol sodium pyruvate l⁻¹, 5 µg gentamicin l⁻¹ and 5 µg ionomycin l⁻¹ (Sigma). After activation, oocytes were incubated for 4.5 h with 6-dimethylaminopurine medium (10 ml TCM-199 supplemented with 2 mmol 6-dimethylaminopurine l⁻¹). At the end of incubation, the oocytes were washed three times in a cleavage medium (IVF cleavage medium; Cook), placed into 50 µl droplets of cleavage medium under mineral oil (Sigma) and incubated for 24 h at 38.5°C and 95% humidity, in an atmosphere containing 5% CO₂ and 5% O₂. All cleaved embryos were cultured further for 8 days in 50 µl droplets of blastocyst medium (IVF blastocyst medium; Cook) under mineral oil. Oocyte morphology and numbers of cleaved oocytes, four- and eight-cell stage embryos, morulae and parthenogenetic blastocysts were assessed visually once a day during the 8 days of culture. Assessment was carried out separately for each cow in each oestrous cycle.

Progesterone analysis

Plasma progesterone concentrations were analysed in a single assay with a solid-phase radioimmunoassay kit (Diagnostic Product Corporation, Los Angeles, CA) against a standard curve prepared in our laboratory by dissolving progesterone in ovariectomized cow plasma, as described previously (Schindler *et al.*, 1990; Shaham-Albalancy *et al.*, 2000). Antibody crossreactivity was 0.2% with 5β-pregnan-3α-ol-20-one and 2% with 20α-dihydroprogesterone. The assay sensitivity was 0.2 ng ml⁻¹ and the intra-assay coefficient of variation was 9.8%.

Statistical analysis

Data on oocyte quality and embryo development collected on day 4 of each oestrous cycle were analysed. The percentages of grade 1 oocytes, cleaved oocytes, four- and eight-cell embryos, morulae and blastocysts from the total number of oocytes recovered were calculated for each cow. In addition, the percentages of morulae and blastocysts from the number of cleaved oocytes were also calculated. As the percentage data did not follow normal distributions, the data were arcsine-transformed before analysis, which was done according to the general linear model procedure of the Statistical Analysis System (SAS, 1987). The statistical model included effects of treatment (treated versus control groups), cows (within treatment) and treatment by cycle interaction. Values are untransformed means ± SEM.

Results

Climatic data for summer, autumn and early winter 1998 are shown (Table 1). From June to September, maximum and minimum temperatures, THI values and the accumulated THI > 72 units were all indicative of severe summer conditions. Oestrous cycle 1 coincided with the warm weather of early October. Thereafter, during oestrous cycles 2, 3 and 4 (mid-October to early December), the cows were under normothermic conditions, as indicated by the low air temperatures and THI values (Table 1). Conception rates after first insemination, which were lowest (6–13%) from early August to early October, remained low (20–30%) in the autumn (late October and November) compared with those in the winter (44%).

The cows maintained good health, provided their normal milk yield and maintained a relatively good body condition score (2.5 on a scale of 1 to 5) for their stage of lactation and level of milk production during the entire experimental period. No clinical reactions to the repeated transvaginal puncturing of follicles were observed. After oestrous cycle 2, one control cow and one treated cow were excluded from the experiment because of their poor yields of follicles on the day of aspiration. As expected, ultrasonographic monitoring (performed during oestrous cycle 2, data not shown) indicated that, in the treated group, repeated removal (every 3–4 days) of all visible follicles > 3 mm in

Fig. 1. Plasma concentrations of progesterone in control ($n = 8$, ●) and treated ($n = 8$, ▲) cows during two consecutive oestrous cycles. Follicular aspiration was performed on day 4 of the oestrous cycle in the control cows and on days 4, 7, 11 and 15 of the oestrous cycle in the treated cows. PGF_{2α} and GnRH were injected on days 19 and 21, respectively, in both groups. Values are mean $\pm$ SEM.

diameter prevented development of dominant follicles between day 0 and day 15. The numbers of medium-size (6–9 mm) and large (> 10 mm) follicles at the follicular phase (day 19) did not differ between control and treated cows (2.7 and 1.9 versus 2.6 and 1.9, respectively). Progesterone concentrations in the plasma did not differ between oestrous cycle 1 and cycle 2 or between experimental groups (Fig. 1). Similarly, the numbers of corpora lutea did not differ between control and treated cows (1.0 and 1.2, respectively). Control cows showed three follicular waves during the oestrous cycles: the first wave emerged 1–2 days after ovulation (day 0); the second wave emerged 1–2 days after follicular aspiration (performed on day 4); and the third wave emerged on days 11–12 of the cycle. In the treated cows, a total of five waves was induced in each of the experimental oestrous cycles. Similar to control cows, the first wave emerged immediately after ovulation and the remaining waves emerged 1–2 days after each of the follicular aspirations, performed on days 4, 7, 11 and 15 of the oestrous cycle.

The mean numbers of follicles aspirated on day 4 of each oestrous cycle and the numbers and percentages of the oocytes recovered did not differ between control and treated cows (Table 2). In oestrous cycle 1, the percentages of grade 1 oocytes, cleaved oocytes, eight-cell embryos and blastocysts were low in both groups (Fig. 2a–d). A treatment by cycle interaction ($P < 0.05$; Fig. 2a) indicated that there was an earlier increase in the percentage of grade 1 oocytes in the treated cows (cycle 2) than in the control cows (cycle 3). The cleavage rate in the treated group increased gradually from about 40% in cycle 1 to about 75% in cycles 3 and 4 ($P < 0.05$), whereas in the control group it fluctuated between 58% and 32% during cycles 1 to 4 (Fig. 2b). This trend was reflected in a treatment by cycle interaction that tended towards significance ($P < 0.08$). The percentages of eight-cell embryos (Fig. 2c) in the control group increased slightly but remained low during the

experiment, and the percentages of blastocysts (Fig. 2d) were almost zero, ranging between 1 and 3%. In contrast, significant main effects of treatment and of treatment by cycle interaction indicated marked increases in the percentages of eight-cell embryos in treated cows in cycles 3 and 4 ($P < 0.05$). Similarly, a significant main effect of treatment on blastocyst formation was detected ($P < 0.05$), reflecting increases in the percentage of blastocysts in treated cows to 10 and 20% in cycles 3 and 4, respectively. For comparison, the percentages of blastocysts calculated from cleaved oocytes in the treated group were 14 and 28% in cycles 3 and 4, respectively. In both control and treated groups, the patterns of change in the percentages of four-cell embryos and morulae during the four cycles were similar to those of eight-cell embryos (Fig. 2c). The mean percentages of four-cell embryos during cycles 1–4 in control and treated cows were 20 ± 5 and $50 \pm 9\%$, respectively ($P < 0.05$). The mean percentages of morulae during cycles 1 to 4 in control and treated cows were 10 ± 3 and $30 \pm 6\%$, respectively ($P < 0.05$).

Discussion

The present study is the first to show delayed effects of summer heat stress on oocyte quality and embryonic development. Another novel finding is that frequent follicular aspiration enhanced the removal of impaired antral follicles and led to the earlier emergence of healthy follicles and high quality oocytes.

The changes in oocyte quality and embryo development occurring from late summer, throughout the autumn until early winter were expressed in the control group. The low oocyte quality at the end of the summer and early autumn (cycle 1) coincided with moderate heat stress and corresponded well with the low fertility recorded during this period. These findings are consistent with previously reported close associations between long-term summer heat stress (Rocha *et al.*, 1998) or short-term acute heat exposure *in vivo* or *in vitro* (Putney *et al.*, 1988; Rivera and Hansen, 2001) and poor embryonic development. However, during the autumn and early winter (cycles 2–4), although the weather was cool, the percentages of grade 1 oocytes increased slightly, but the cleavage rate did not increase and the percentages of four- and eight-cell embryos and morulae remained relatively low, indicating a carry-over effect of previous heat exposure. However, the changes in the control group were not accompanied by an increase in blastocyst development, which remained very low even during early winter (cycle 4), compared with 30% of blastocysts that developed in the treated group. This finding is surprising, because the delayed effect of summer heat stress in terms of fertility data is, by definition, transient. Indeed, in a similarly designed study using identical methodology, performed a year later under milder summer conditions, a significantly higher percentage of blastocyst development was noted in the early winter than in the autumn (52 versus 11%, respectively; Z. Roth, A. Arav and

D. Wolfenson, unpublished). It is likely that the exceptionally severe summer conditions in 1998, which extended to early October, prevented blastocyst development in the early winter as well. The above findings indicate that the extent of deterioration of oocyte quality in the autumn and the time needed for recovery of quality may depend on the duration and severity of the thermal stress to which cows were exposed in the previous summer. It is worth noting that the carry-over effect of heat stress on oocyte quality reported and discussed in the present paper could affect not only oocytes that develop in the cool autumn, but also those that develop during the long-term summer heat stress. For example, the limited increase in pregnancy rate achieved through short-term, intensive cooling during the first week after insemination in the summer (Her *et al.*, 1988; Ealy *et al.*, 1994) probably reflects the detrimental effect of heat stress on follicular or oocyte function before the application of cooling.

Studies on heifers and cows have found that impaired oocyte quality in the early postpartum period is associated with a negative energy balance and low body condition (Kendrick *et al.*, 1999; Snijders *et al.*, 2000). It has been claimed that a postpartum period of about 90 days is

needed to obtain high quality oocytes (O'Callaghan *et al.*, 1999; Gwazdauskas *et al.*, 2000). It was necessary to eliminate the possibility that the impairment of oocyte quality was associated with the metabolic status of the cows examined to confirm that the impairment of oocyte quality in the autumn, documented in the present study, resulted from previous exposure to summer heat stress. Accordingly, the cows were at day 90 after parturition at the beginning of the present study to exclude possible postpartum effects, and maintained a relatively good body condition score. Cows at this stage of lactation are cyclic and usually maintain a positive energy balance (Moallem *et al.*, 1999). Furthermore, in contrast to the findings in the present study, it has been found that during the winter, cows at days 70–150 after parturition yielded high rates of grade 1 oocytes and blastocysts (78 and 45%, respectively; G. Inbar, D. Wolfenson and A. Arav, unpublished). Furthermore, the possibility that exposure of cows to thermal stress in the summer impaired their metabolic status and lowered the postpartum body condition more in the autumn than in other seasons can also be eliminated. For example, in large-scale seasonal surveys of high-yielding dairy cows in Israel (Reches *et al.*, 2000) and in a study on lactating cows in

Fig. 2. Percentages of (a) grade 1 oocytes, (b) cleaved oocytes, (c) eight-cell embryos and (d) blastocysts, calculated from recovered oocytes, in control ($n = 7-8$, □) and treated ($n = 7-8$, ■) cows. Follicular aspiration was performed on day 4 of the oestrous cycle in the control cows and on days 4, 7, 11 and 15 of the oestrous cycle in the treated cows. PGF_{2α} and GnRH were injected on days 19 and 21, respectively, in both groups. Oocytes were recovered on day 4 of four consecutive oestrous cycles in late summer (cycle 1), autumn (cycles 2 and 3) and early winter (cycle 4), after exposure to summer heat stress. A treatment by cycle interaction was detected for grade 1 oocytes ($P < 0.05$). Cleavage rates differ between treatments in cycles 3 and 4 ($P < 0.05$). A main effect of treatment and a treatment by cycle interaction were detected for eight-cell embryos ($P < 0.05$). A main effect of treatment was detected for blastocysts ($P < 0.05$). Values are mean $\pm$ SEM.

Australia (Jonsson *et al.*, 1997), no differences in body condition scores at calving or after parturition were detected between cows calving in summer and in winter. Collectively, the above findings indicate that the poor oocyte quality and embryo development in the autumn, as recorded in the present study, resulted from the hyperthermia induced during the previous exposure to summer heat. It is less likely that alteration in metabolic status or of stage of lactation after parturition are involved in low oocyte quality.

Oocytes are susceptible to thermal stress (Edwards and Hansen, 1997; Rivera and Hansen, 2001), but the mechanism by which heat stress impairs oocyte quality is less clear. Oocyte membrane characteristics, such as fatty acid composition, and physical properties such as lipid phase transition, are altered by exposure to low temperatures or to high temperatures during long-term summer heat stress (Arav *et al.*, 1996; Zeron *et al.*, 2001). However, it is not

known whether such cellular changes persist from the summer into the autumn. Roth *et al.* (2001) found that a delayed effect of heat stress on steroidogenesis in thecal and granulosa cells was related to previous exposure of antral follicles of about 0.5–1.0 mm in diameter to thermal stress. At such an early antral stage of follicular development, bovine oocytes are still in the growth phase, which is characterized by intensive RNA synthesis (Fair *et al.*, 1995, 1996) and might be particularly sensitive to environmental changes. Another possibility is impairment of cell–cell communication between granulosa and cumulus cells, and between cumulus and oocyte, which might impair oocyte competence. In addition, the delayed impairment of oocyte function in heat-stressed cattle may result from alteration in the contents of follicular fluids such as insulin-like growth factor binding proteins (IGFBPs; Ambrose *et al.*, 1999) or steroids (Wolfenson *et al.*, 1997). A delayed deleterious effect of heat exposure on steroidogenesis of thecal and

granulosa cells has been recorded, which corresponded to decreased follicular fluid oestradiol concentrations in the autumn (Roth *et al.*, 2001). Such a decrease may affect secretion of gonadotrophins and could be involved in alteration of acquisition of meiotic competence.

The frequent follicular aspiration to which the treated group was subjected in the present study induced an earlier recovery of oocyte quality in the autumn. Such improvement probably resulted from enhanced removal of a pool of follicles that had been damaged in the previous summer. Bovine ovaries contain about 250 very small antral follicles measuring 0.6–0.9 mm in diameter (Miyamura *et al.*, 1996). In our previous study, this stage of folliculogenesis was hypothesized to be susceptible to heat stress (Roth *et al.*, 2001). Thus, it could be assumed that long-term exposure to summer heat stress during the early stages of follicular development had impaired this pool of small antral follicles that, nevertheless, continued to grow to 3–7 mm in diameter and were aspirated during the autumn. This transient pool of damaged follicles, which emerged during the autumn, would be removed naturally from the ovaries during three to four consecutive cycles, as occurred in the control group; their removal was also reflected in the fertility data. However, the frequent follicular aspirations performed in the present study induced the emergence of two extra follicular waves per cycle in the treated cows (a total of eight extra follicular waves during the entire experiment). An average follicular wave comprises about 24 small (3–4 mm in diameter) antral follicles (Ginther *et al.*, 1996); therefore, it is estimated that in the present study about 200 more follicles emerged and were removed in the treated group than in the control group. This estimate does not differ greatly from the figures presented by Miyamura *et al.* (1996).

Frequent follicular aspiration *per se* is less likely to improve oocyte quality, irrespective of the removal of a pool of defective follicles, as suggested above, for the following reasons. Firstly, in the present study, frequent follicular aspiration performed in cycle 1 failed to improve any stage of embryo development in the treated cows (cleavage, four- and eight-cell embryos, morulae or blastocysts) during the subsequent cycle (cycle 2); improvement was evident only later, in cycles 3 and 4, after aspiration of additional impaired follicles. Secondly, experiments that were not associated with heat stress conditions, unlike the present study, have shown that oocytes of high quality at the beginning of various studies were unaffected by long-term, frequent follicular aspiration (Kruip *et al.*, 1994; Bols *et al.*, 1998); sometimes the percentage of developed embryos decreased over time (Kruip *et al.*, 1995). Thirdly, other studies have found that twice-weekly follicular aspiration led to more viable oocytes than did once-weekly aspiration, and that the increase was associated with the elimination of dominance and the aspiration of small follicles rather than medium-sized follicles that may already be degenerating when collected under a once-weekly protocol (Garcia and

Salaheddine, 1998; Goodhand *et al.*, 1999). However, in the present study, although follicular aspiration in the treated group was performed twice a week compared with once per cycle in the control group, the comparison between treated and control groups was valid as oocyte quality was assessed on day 4 of each cycle in both treated and control groups, before the onset of any detrimental effect of the first-wave dominant follicle on the subordinate follicles. Furthermore, aspiration on day 4 of each cycle was performed in both control and treated groups, both of which had followed similarly normal patterns of growth and regression of corpora lutea, induction of follicular phases, growth of dominant preovulatory follicles and ovulation in the previous cycles. Collectively, these factors indicate that frequent follicular aspiration did not have any beneficial effect on oocyte quality in the treated cows, other than faster removal of defective follicles from the ovary. However, despite the points discussed above, it could be argued that the pool of follicles that were aspirated on day 4 of the cycle might have been influenced by an extensive period of less follicular dominance during the previous cycle. Additional examination of the effect of frequent follicular aspiration on oocyte quality should be performed during the winter on cows that had not been exposed to heat stress during the preceding season to clarify this matter further.

In conclusion, the present study provides clear evidence for a delayed effect of summer heat stress on oocyte quality. Enhanced removal of the impaired cohort of follicles during the autumn led to earlier emergence of healthy follicles and higher quality oocytes. Hormonal treatment that would enhance the emergence of more follicles or induce more follicular waves could improve autumn fertility of cows in warm climates.

The authors would like to thank A. Ocheretny for her technical assistance and NIADDK-NIH for provision of LH and FSH.
