Introduction

There is increasing evidence that cells in mammalian preimplantation embryos undergo apoptosis (for a review, see Hardy, 1997; Betts and King, 2001). Characteristic apoptotic features, including fragmenting nuclei and nuclei with fragmented DNA, are rarely seen before compaction, but are commonly seen in blastocysts from a number of mammalian species, including humans (Hardy, 1999; Hardy et al., 2001), mice (Handyside and Hunter, 1986; Brison and Schultz, 1997) and cows (Byrne et al., 1999; Matwee et al., 2000). Levels of apoptosis can be environmentally regulated (Brison and Schultz, 1997; Pampfer et al., 1997; Moley et al., 1998; Spanos et al., 2000) but the role remains unknown (Hardy, 1997).

Two major protein families are central to the regulation and execution of apoptosis, the BCL-2 and caspase families, which are highly conserved from worms to humans (Aravind et al., 1999). The caspase family of cysteine proteases mediates proteolytic cleavage of a large number of proteins leading to the apoptotic morphology observed in cells, including the formation of fragmented nuclei and apoptotic bodies (Earnshaw et al., 1999). Each caspase is synthesized as an inactive precursor, which is activated only after a cell has received a death signal. Activated upstream caspases, known as initiator caspases, activate downstream executor caspases (which cleave proteins important for cell survival and integrity) and endonucleases (which cleave DNA) (Nagata, 2000).

The BCL-2 family, which is involved in the regulation of caspase activity, is subdivided into pro-apoptotic (for example BAX and BAD) and anti-apoptotic BCL-2 was examined in single embryos using RT–PCR and immunohistochemistry. BAX and BCL-2 mRNAs were expressed throughout development, whereas BAD mRNA was expressed mainly after compaction. Simultaneous expression of BAX and BCL-2 proteins within individual embryos was confirmed using immunohistochemistry. The onset of caspase activity and BAD expression after compaction correlates with the previously reported appearance of apoptotic nuclei. As in other types of cell, human embryos express common molecular components of the apoptotic cascade, although apoptosis appears to be suppressed before compaction and differentiation.
by pore formation (Vieira and Kroemer, 1999; Tsujimoto and Shimizu, 2000; Bernardi et al., 2001). Apoptotic mitochondrial changes are mainly prevented by anti-apoptotic proteins, such as BCL-2, located in the outer mitochondrial membrane, as well as the nuclear envelope and endoplasmic reticulum. However, during apoptosis, pro-apoptotic members (for example BAX and BAD) are activated, translocating from the cytosol to the mitochondria (Hsu et al., 1997; Wolter et al., 1997). In this way, the BCL-2 family of proteins is believed to regulate the release and activation of pro-apoptotic factors from mitochondria, such as cytochrome c and apoptosis-inducing factor, that lead to the activation of caspases and other downstream execution proteins and ultimately cell death.

Until recently, little was known about the expression of the BCL-2 and caspase families in preimplantation embryos. In the mouse, mRNAs for anti-apoptotic Bcl-2, Bcl-xL and Bcl-w and pro-apoptotic Bax, Bak, Bad and Bcl-xL were found throughout preimplantation development (Jurisicova et al., 1998; Warner et al., 1998b; Exley et al., 1999), and Bax and Bcl-2 protein is found in mouse and rat blastocysts, respectively (Moley et al., 1998; Pampfer et al., 2001). Both Bax and Bcl-2 play a role in the regulation of apoptosis in the rodent preimplantation embryo; mouse blastocysts deficient in Bax and rat blastocysts with antisense-blocked Bcl-2 expression are resistant to high-glucose-induced apoptosis (Moley et al., 1998; Pampfer et al., 2001). Expression of mRNA for caspases 2, 3, 6, 7 and 12 was also found throughout mouse preimplantation development (Exley et al., 1999).

Little is known about the expression of these regulatory proteins in human embryos. Both mRNA and protein for BAX and BCL-2 have been found in early uncompact embryos (Warner et al., 1998a; Antczak and Van Blerkom, 1999; Liu et al., 2000), but there is no information about expression at the morula and blastocyst stages.

The present study examined for the first time the expression of mRNA for BCL-2, BAX and BAD and immunohistochemically localized BCL-2 and BAX in human embryos through development from the two- to four-cell stage to the blastocyst stage. BCL-2 and BAX were examined as they are representative and widely expressed examples of anti- and pro-apoptotic members of the BCL-2 family that are involved in the regulation of apoptosis in rodent embryos, and the ratio of which is thought to determine the fate of the cell. Expression of BAD was investigated because of its central role as a key mediator in the apoptotic pathway triggered by growth factor deprivation, such as the insulin-like growth factor 1 (IGF-I)-regulated pathway (Spanos et al., 2000). Finally, the hypothesis that caspases are involved in generating the classic apoptotic morphology commonly seen after compaction in human embryos (Hardy et al., 2001) was investigated.

Materials and Methods

Human oocytes and embryos

Oocytes and embryos were donated with informed consent by infertile couples undergoing IVF, who did not wish to cryopreserve untransferred embryos for future replacement. The work was conducted under licence from the Human Fertilisation and Embryology Authority (HFEA) and local ethical permission was granted by the ethics committee of Imperial College School of Medicine, Hammersmith Hospital, London.

Superovulation and IVF were carried out as described by Spanos et al. (2000). Approximately 16–18 h after insemination (day 0 = day of insemination), oocytes were classified according to the number of visible pronuclei. Embryos were initially cultured individually in 1 ml of Earle’s balanced salt solution (EBSS; Gibco BRL, Paisley) containing 5.56 mmol glucose l–1, 25.0 mmol sodium bicarbonate l–1 (BDH, Lutterworth), 0.47 mmol pyruvate l–1 (Sigma, Poole), 37.5 U streptomycin ml–1 (Sigma) and 97.5 U penicillin ml–1 (Sigma) and supplemented with 10% heat-inactivated maternal serum, under a gas phase of 5% CO2, 5% O2 and 90% N2 at 37°C.

On the morning of day 2, embryos were graded on the basis of blastomere symmetry and degree of fragmentation (Dawson et al., 1995). Oocytes that were unfertilized on day 2 and two pronucleate arrested and developing embryos of various morphologies were selected for study. From day 2, embryos were cultured individually in 5 μl droplets of custom-made glucose-free EBSS supplemented with 1 mmol l-glutamine l–1 (Sigma) (Devreker et al., 1998) and 4 mg IGF-free BSA ml–1 (Sigma) (Spanos et al., 2000), overlaid with silicone fluid (Dow Corning 200/50cS; BDH). Culture media were prepared weekly from stock solutions and stored at 4°C before use. Embryos were transferred to fresh 5 μl droplets of culture medium at 24 h intervals. All oocytes and embryos were monitored and treated individually throughout the entire experimental procedure.

Some cryopreserved embryos were used as part of the active caspase labelling study. Twenty embryos that had been cryopreserved between day 1 and day 3, and that had contained two pronuclei on day 1, were thawed. The embryos were donated for research with informed consent. Frozen embryos in straws were removed from liquid nitrogen and placed in a 37°C waterbath for 30 s. Embryos were then flushed into 1.0 mol 1,2-propanediol l–1 (Sigma) in PBS (Gibco BRL) supplemented with 8 mg BSA ml–1 (Sigma) (PBS–BSA) at room temperature and incubated for 5 min, before being taken through a series of thawing solutions: 0.5 mol 1,2-propanediol l–1 in PBS–BSA (5 min); 0.2 mol sucrose l–1 in PBS–BSA (Analar, BDH) (10 min); PBS–BSA alone (10 min). After the final incubation in PBS–BSA, embryos were examined for thawing damage. Surviving embryos with intact blastomeres were cultured as described above in 5 μl droplets of glucose-free EBSS under silicone fluid for ≈ 24 h. Surviving embryos of good morphology that cleaved during culture after thawing were cultured to various stages before labelling for active caspases.

Reverse transcription (RT)

All chemicals were from Sigma unless otherwise stated. After zona pellucida removal with acid Tyrode’s (pH...
Expression of apoptotic genes in human embryos

2.3–2.4) (ZD™-10 Scandinavian IVF Science AB; Hunter Scientific Ltd, Saffron Walden), individual oocytes and embryos were washed in sterile PBS and lysed in 5 µl lysis buffer (0.5% IGEPAL CA-630, 10 mmol Tris l⁻¹ (pH 8.0), 10 mmol NaCl l⁻¹ and 3 mmol MgCl₂ l⁻¹) on ice (Gilliland et al., 1990). If reverse transcription was not carried out immediately, lysates were snap frozen in liquid nitrogen and stored at −70°C for a maximum of 2 weeks. The lysate was made up to 20 µl with 1 µl of a 10 mmol dNTP mix l⁻¹ (100 µl each of 100 mmol dATP l⁻¹, dUTP, dCTP and dGTP (Pharmacia, New Jersey) in 600 µl RNase-free water), 2 µl of 0.1 mol dithiothreitol l⁻¹ (DTT; Gibco BRL), 1 µl of 5 × first strand buffer (Gibco BRL), with and without (negative control) 1 µl (200 U µl⁻¹) Moloney Murine Leukemia Virus (M-MLV) reverse transcriptase (Gibco BRL) and 1 µl (0.5 µg) oligo(dT)₁₂₋₁₈ primer (Gibco BRL) before incubation at 37°C for 1 h. The reaction was terminated by heating the tubes at 99°C for 5 min before immediately placing on ice. All tubes were centrifuged at 10,000 g for 1 min and the supernatant was used for nested PCR, or stored at −20°C until further use.

Nested RT–PCR and gel electrophoresis

Oligonucleotide primer pairs derived from human sequences of BCL-2, BAX and BAD were designed using Primer3 Output (http://www.genome.wi.mit.edu/genome_software/other/primer3.html) and synthesized chemically (Oswel, Bassett Crescent East, Southampton). Primer pairs derived from the cloned sequence for human β-actin (Ponte et al., 1984) were included as a positive control to evaluate the quality of the cDNA prepared from the oocytes and embryos, the PCR procedure and to test for genomic contamination. All primers spanned introns so that product derived from contamination with genomic DNA would be larger than the cDNA product of RT–PCR. Oligonucleotide primer pairs, annealing temperatures and expected sizes of amplified PCR products are summarized (Table 1). Granulosal or placental cDNA was used as a positive control.

After reverse transcription, 5 µl of reverse transcribed cDNA product was made up to 50 µl with 5 µl of 10 × PCR buffer II (Applied Biosystems, Roche, Welwyn Garden City), 0.5 µl of 10 mmol dNTP mix l⁻¹, 3 µl of 25 mmol MgCl₂ solution l⁻¹ (Applied Biosystems), 0.5 µl (5 U µl⁻¹) Taq polymerase (Applied Taq; Perkin Elmer, Roche, Beaconsfield) and 1 µl of each 40 ng primer ml⁻¹. PCR conditions were denaturation at 94°C for 1 min, annealing at the temperature specified for each primer set (Table 1) for 1 min, extension at 72°C for 90 s and a final extension of 6 min. PCR was carried out using a PCR express thermal cycler (Hybaid Ltd, Ashford). The outer primers were run for 25 cycles, and nested primers for 30–35 cycles. For the nested reaction, 5 µl of the first amplification product was added to freshly prepared PCR mix. Ten microlitres of each amplification product was separated on 2% (w/v) agarose gel (Gibco, BRL), stained with ethidium bromide (Sigma) and photographed under UV light. PCR products were verified using restriction digest analysis (Table 1) and sequencing.

Immunohistochemistry

Two pronucleate embryos at different stages were processed individually for immunohistochemistry. All PBS was filtered with a 0.22 µm filter (Millipore, Watford). Single embryos were washed twice in approximately 100 µl filtered PBS supplemented with 3 mg polyvinylpyrrolidone ml⁻¹ (PVP; Sigma) (PBS–PVP, pH 7.4). Embryos were fixed with 4% (w/v) paraformaldehyde (Sigma) (1 h at room temperature) before washing twice with PBS–PVP and staining with 1% (w/v) eosin (Merck, West Drayton) aqueous solution (30 s) to facilitate visualization of the embryo during sectioning. Embryos were then placed individually in 2% (w/v) liquid agarose gel (low gelling temperature < 30°C) (Sigma) and left overnight at room temperature to set. A small section of the gel containing the embryo (approximately 3 mm × 3 mm) was excised with a scalpel, dehydrated through a series of alcohol (Analar, BDH: 70%, 1.0 h; 90%, 1.0 h; 100%, 1.5 h) and placed in xylene (Histoclear; National Diagnostics, Hessel) for 1 h. Specimens were embedded in paraffin wax (Surgipath Europe Ltd, Peterborough), cut into serial sections (5 µm) and retrieved on poly-L-lysine-coated microscope slides (BDH). Paraffin wax was removed from the sections in three changes of xylene (10 min each) and the sections were then hydrated through a series of alcohol (Analar, BDH: 10 min each 100%, twice; 90%, twice; 70%, twice; and finally 5 min in distilled water, twice).

Individual dewaxed sections from each embryo were distributed equally between control (no primary antibody), and staining for BAX and BCL-2, using rabbit polyclonal antibodies (Oncogene Research Products, CN Biosciences (UK) Ltd, Beeston, Nottingham). Antibodies were used at a dilution of 2 µg ml⁻¹ (1:50 dilution, as determined by dilution curve) in 1% PBS–BSA. All incubations were carried out in a humidified chamber at ambient temperature (unless otherwise stated). Sections were incubated for 10 min in 0.1% (v/v) hydrogen peroxide (Merck) in water to quench endogenous peroxidase activity, washed with PBS (5 min), incubated with blocking serum (UniTect Immunohistochemistry detection system; Oncogene Research Products) (20 min), washed again with PBS and then incubated overnight at 4°C with the primary antibody. Sections were rinsed three times in PBS (5 min each) before the addition of biotinylated horse anti-rabbit IgG secondary antibody (UniTect) diluted according to the manufacturer’s instructions, for 30 min, and then washed three times in PBS followed by application of peroxidase-conjugated avidin–biotin complex (Unitect) for 30 min. Sections were washed in five changes of PBS, rinsed in 1% (v/v) Triton-X100–PBS (Sigma) (30 s) and visualized with 3, 3¢-diaminobenzidine tetrahydrochloride (DAB; Dako Corporation, Carpentry) (30–90 s) and with Harris’ haematoxylin (BDH) as a counterstain. Sections were dehydrated through a 70%, 90% and 100% ethanol series as described previously and mounted in DPX (BDH). The specificity of BAX and BCL-2 labelling was checked by: (i) parallel staining for antibodies.
in mouse gut sections (positive controls); (ii) omitting the primary antibody (negative control); and (iii) peptide competition experiments using peptide concentrations of 10, 100, 200, 500 and 1000 m\(g\) ml\(^{-1}\). A 1:200 dilution of BAX peptide markedly reduced immunohistochemical labelling of BAX and dilutions of 1:20 and 1:2 completely obliterated any labelling. BCL-2 labelling was reduced at 1:20 dilution and completely prevented at a 1:2 dilution of BCL-2 peptide.

Sections were examined using an Eclipse TE300 inverted light microscope (Nikon UK, Kingston-upon-Thames). Images were captured at the same light intensity using a DXM1200 digital camera (Nikon UK) and Lucia™ digital image analysis software (Nikon UK). The intensity of staining was graded from – (no staining; equivalent to control sections) to + (pale staining), ++ (moderate staining) and +++ (darkest staining intensity).

Caspase activity labelling

CaspTag™ fluorescein caspase activity kit (Intergen, Oxford Science Park, Oxford) was used to detect active caspases in failed-fertilized aged oocytes (days 3–6) and fresh or frozen–thawed embryos. The kit uses a carbobylfluorescein (FAM)-labelled broad-spectrum caspase inhibitor FAM–VAD–FMK, which is a potent inhibitor of caspase-3 and caspase-3-like caspases. It enters the cell and irreversibly binds to activated caspase-3, -8, -7, -10 and -6 in the order of decreasing activity, labelling them and allowing them to be visualized and localized.

After culture, embryos or oocytes were transferred to a 96-well, U-bottomed tissue culture plate (Falcon, Becton-Dickinson) and washed twice in approximately 100 ml PBS–PVP. The zona pellucida was removed with a brief incubation in acid Tyrode’s solution at room temperature and embryos were washed once more in PBS–PVP. Zona pellucida-free embryos and oocytes were incubated for 1 h at 37°C under 5% CO\(_2\) in 10 ml labelled caspase inhibitor (Caspataq; Intergen) and reconstituted in EBSS (according to manufacturer’s instructions). Specimens were then fixed using 4% (w/v) paraformaldehyde (Sigma) for 1 h. Positive controls were incubated in 1 mmol staurosporine l\(^{-1}\) (Sigma) overnight at 37°C and washed in PBS–PVP before labelling for caspase activity. After labelling, embryos were washed twice in PBS–PVP, mounted in Vectashield with 4,6-diamidino-2-phenylindole (DAPI) (1.5 gm l\(^{-1}\)) (Vector Laboratories, Peterborough) and stored in the dark at 4°C before two channel laser scanning confocal microscopy using a Leica TCS NT-SP-UV laser scanning confocal microscope (Leica, Milton Keynes).

Results

Detection of BAX, BCL-2 and BAD mRNA

Expression of BAX, BAD and BCL-2 mRNA was studied in 78 failed-fertilized oocytes and preimplantation embryos at the two- to eight-cell, morula and blastocyst stages (Fig. 1, Table 2). Beta actin expression was detected in unfertilized oocytes and at all stages of preimplantation development. The embryos had two pronuclei on day 1, were not arrested and were developmentally on schedule. The expected 250 bp and 209 bp fragments encoding BAX and BCL-2 cDNA, respectively, were detected at the single oocyte and embryo level during all stages of preimplantation development.

Fig. 1. Expression of mRNA for BAX, BCL-2, BAD and beta-actin in individual human oocytes and embryos at all preimplantation stages of development. Lanes: M: 1 kb DNA ladder; O: oocyte; 2: two-cell embryo; 4: four-cell embryo; 8: eight-cell embryo; B: blastocyst; +: PCR positive control (fetal tissue cDNA); –: RT negative control.
Development (Fig. 1, Table 2). However, transcripts encoding BAD were detected mainly after compaction (Fig. 1), although there was occasional amplification in early embryos (Table 2). The identity of the PCR products was confirmed by sequence and restriction digest analysis.

Detection of BAX and BCL-2 protein

Twenty-two arrested and developing embryos (which had showed two pronuclei on day 1) were analysed for BAX and BCL-2 protein expression using immunohistochemistry. In the absence of primary antibody, no labelling was detected (Fig. 2). Control sections of mouse intestine showed intense labelling for BAX and BCL-2 (data not shown). Both BAX and BCL-2 proteins were expressed in human embryos at the two- to eight-cell, morula and blastocyst stages (Fig. 2, Table 3). Generally, embryos of poor morphology had higher expression of both BAX and BCL-2 (Table 3). Within each embryo, staining for BAX and BCL-2 was heterogeneous (Fig. 2), demonstrating that each protein is differentially expressed in different cells.

Caspase activity in human embryos

Ten unfertilized oocytes, 22 arrested and 36 developing embryos were examined for the presence of active caspasases (Table 4). In embryos that were developing on schedule, caspase activity was not evident before compaction and morula formation, with the exception of the polar bodies, which were intensely stained (Fig. 3, Table 4). Labelling of active caspasases was absent in both fresh and frozen–thawed embryos before compaction. After compaction, > 50% of morulae had one or more caspase-positive cells, and most (> 90%) of the blastocysts had cells with caspase activity. There was no qualitative difference in the amount of caspase labelling between morulae and blastocysts grown from fresh or cryopreserved embryos (Table 4). Anucleate cytoplasmic fragments were often labelled. In many cases the caspase labelling was associated with fragmented nuclei.

A small proportion of the arrested embryos examined had cells with active caspase labelling at the two- to four-cell stage (approximately 10%) and five- to eight-cell stage (approximately 20%) (Table 4). Two of these embryos (both fresh), one two- and one four-cell stage, were labelled on day 5 and had been arrested for > 3 days.

Discussion

The present study has demonstrated, in human embryos, the expression of three major regulatory genes involved in apoptosis. BAX and BCL-2 mRNA and protein are expressed in unfertilized oocytes and throughout preimplantation development, whereas BAD mRNA is expressed mainly after compaction. Generally, amounts of BAX and BCL-2 protein are higher in embryos of poor morphology, with intense BAX staining in some fragments. Active caspasases, the executors of cell death, are present after compaction in some morulae and most blastocysts, and are frequently associated with apoptotic nuclei.

Before compaction, BAD was undetectable in most embryos using the techniques described. However, transcripts were detected in most morulae and all blastocysts. This finding indicates that the embryo starts to express embryonic BAD after activation of the embryonic genome. This expression coincides with the appearance of DNA and nuclear fragmentation (characteristic of apoptosis) following compaction (Hardy et al., 2001), indicating that BAD is a key regulatory protein in preimplantation apoptosis. BAD is central in the anti-apoptotic action of growth factors, such as IGF-I, which acts via the phosphatidylinositide 3'-OH kinase pathway (Datta et al., 1999). In other types of cell it has been shown that growth factor stimulation maintains BAD in a phosphorylated inactive state sequestered in the cytosol. Growth factor deprivation results in decreased PI-3 kinase pathway activity and BAD becomes dephosphorylated, allowing it to enter mitochondria, promoting apoptosis. In human embryos, IGF-I has been shown to reduce apoptosis and increase blastocyst formation (Spanos et al., 2000).

These findings confirm observations in mouse

Numbers in parentheses represent the number of embryos expressing mRNA for gene of interest/number of embryos examined. Some embryos were analysed for more than one mRNA. na: not analysed.
Fig. 2. Immunohistochemical localization of BCL-2 and BAX in two pronucleate human preimplantation embryos. Each row consists of sections from the same embryo. Left hand column: control; middle column: BCL-2; right hand column: BAX. Insets in control sections are light micrographs of embryos before fixation. (a) Day 4 eight-cell embryo of good morphology. Note
preimplantation embryos. Bcl-2 and Bax transcripts were detected at all stages examined from the zygote to the blastocyst (Jurisicova et al., 1998; Warner et al., 1998b; Exley et al., 1999). Exley et al. (1999) were unable to detect Bad mRNA in mouse embryos, but small amounts were occasionally detected in oocytes. Jurisicova et al. (1998) detected small amounts during cleavage, and there was an increase in expression at the blastocyst stage. This finding is

fragment with intense BAX labelling (arrowhead). (b) Day 4 cleavage stage embryo of poor morphology with extensive fragmentation. (c) Day 4 morula with excluded cells. Note pale BAX staining except for fragments (arrows, inset). (d) Day 4 blastocyst of good morphology. Note paler BAX labelling compared with (e). (e) Day 5 blastocyst of poor morphology. Note heterogeneous expression of BAX labelling (arrowhead).

^aDay 0 = day of insemination. 

^bValues are mean ± SEM (n = number of embryos for which it was possible to accurately determine number of cells). 

n = number of embryos examined.
Fig. 3. Confocal projections showing fluorescent labelling of active caspases in human preimplantation embryos. Nuclei, labelled with 4,6-diamino-2-phenyline (DAPI), are artificially coloured in red for clarity; cells and fragments labelled for...
similar to the observations in the present study of occasional expression (12% of embryos) before compaction, and more consistent expression in morulae and blastocysts. In addition, mouse embryos have been shown to express a range of caspase-related genes (Exley et al., 1999). Collectively, this evidence supports the theory of a ‘universal’ mechanism of apoptosis that occurs during early embryogenesis as well as in many other types of cell.

Caspase activity appears only after compaction in both fresh and frozen–thawed embryos. Generally, active-caspase-positive cells are correlated with nuclear fragmentation. The present study has shown that the timing of expression of active caspases coincided with the onset of BAD expression and also with the onset of apoptosis reported by Hardy et al. (2001). Weil et al. (1996) reported that early embryos were more resistant to induced apoptosis than were cells in the blastocyst and hypothesized that a functional apoptotic pathway may be suppressed during early development (Weil et al., 1996). The expression of apoptosis genes throughout mouse and human preimplantation development (this study and Exley et al., 1999), coupled with the late onset of morphological signs of apoptosis after compaction or even blastocyst formation in a variety of species (Brison and Schultz, 1997; Long et al., 1998; Byrne et al., 1999; Hardy et al., 2001), certainly supports the hypothesis that although the apoptotic machinery is present throughout development, apoptosis is inhibited during early cleavage stages. Possible candidates for suppressing apoptosis during early cleavage include inhibitors of apoptosis (IAPs), which directly inhibit active caspases (Goyal, 2001).

The general absence of morphological signs of apoptosis before compaction or blastocyst formation in mammalian embryos is intriguing. It is possible that, in contrast to cells in the blastocyst, in which phagocytosis has been observed (Hardy et al., 1996), cleavage stage blastomeres do not have the ability to phagocytose dying cells. The final ‘clearing away’ of cell debris by phagocytosis is a crucial step in the apoptotic pathway and if it does not occur the apoptotic cells could lyse, and their caspase-packed cytoplasm could damage adjacent healthy cells (Henson et al., 2001). It is possible that in the absence of an efficient waste disposal system, it is too dangerous to the health of the embryo as a whole to risk release of lytic cell contents from dying cells within the close confines of the zona pellucida. Large, arrested cells can persist in the blastocoel or between the trophoectoderm and the zona pellucida (Hardy, 1999), providing evidence that cleavage stage blastomeres are incapable of phagocytosis and removal of these cells.

There are a number of other possible reasons why apoptosis does not start until after compaction. The morula stage is a critical developmental stage which follows activation of the embryonic genome and immediately precedes blastocyst formation with the formation of the first differentiated types of cell. Gap junctions and other junctions only start to be extensively expressed at compaction (Fleming et al., 1992; Hardy et al., 1996). Recently, gap junctions were shown to propagate apoptotic signals between cells (Lin et al., 1998), and a specific gap junction protein (connexin 31.1) was shown to be uniquely expressed in atretic follicles in the mouse ovary (Wright et al., 2001). These observations indicate that the establishment of cell–cell communication may be important in the onset of apoptosis.

Finally, it is becoming clear that cell cycle progression and apoptosis are closely linked, and that apoptosis is induced when cell division and cell cycle progression have ‘gone astray’ (Los et al., 2001). Binucleate cells, probably produced by a failure of cytokinesis (Hardy et al., 1993), and chromosomally abnormal cells, resulting from post-zygotic mitotic non-disjunction (Handyside and Delhanty, 1997), are common throughout preimplantation development. It is unclear whether these cell cycle anomalies are genetic in origin or result from a suboptimal environment. Thus, cell cycle defects are common during preimplantation development and may be linked to increasing amounts of apoptosis, particularly after compaction.

The link between apoptosis and embryo quality is complex. Cytoplasmic fragments are common in human embryos (Alikani et al., 1999) and it has been proposed that they are equivalent to apoptotic bodies as they can contain fragmented DNA (Jurisicova et al., 1996) and express active caspases (Exley et al., 1999; Xu et al., 2001). However, failure to (i) consistently observe apoptotic markers in cytoplasmic fragments (Antczak and Van Blerkom, 1999), (ii) reduce fragmentation with caspase inhibitors (Xu et al., 2001) and (iii) observe active caspases in all fragments (this study) all support the contention that apoptosis and cytoplasmic fragmentation are not always related. Fragments that have persisted for some time may undergo secondary necrosis, with membrane and DNA changes indistinguishable from those seen during apoptosis. The occurrence of apoptotic cells in vivo (Handyside and Hunter, 1986) indicates that apoptosis plays a role in normal development,

Caspase activity are shown in green. Light micrographs of embryos before labelling are shown in insets. (a) Day 5 arrested germinal vesicle (GV) stage oocyte with entire ooplasm stained positive for caspase activity. Note punctate staining. (b) Day 2 four-cell embryo with labelled polar bodies (arrow). (c) Day 3 eight-cell embryo of excellent morphology with nine nuclei and only the polar bodies labelled for caspase activity (arrow). (d) Day 3 compacting embryo with 15 nuclei showing one caspase-labelled cell (arrow). (e) Early blastocyst with 11 nuclei. Although none of the cells are positive, anucleate fragments (arrows) are stained positively for caspase activity. Note multilaminate blastomere (m), binucleate cells (bc) (one of which is positively labelled for active caspases), mitotic cell (*) and caspase labelled cells and blebs (arrows). (f) Day 6 blastocyst with 31 nuclei with cells labelled positive for caspase activity (arrows). (h) Enlarged confocal projection of a caspase-labelled cell with fragmented nucleus (fn) from day 6 expanded blastocyst (g).
although amounts can be increased under suboptimal culture conditions (Brison and Schultz, 1997; Devreker and Hardy, 1997; Pampfer et al., 1997; Moley et al., 1998; Spanos et al., 2000). Thus, suboptimal culture conditions could increase rates of apoptosis to a level at which embryo development and pregnancy outcome is compromised.

The present study has demonstrated that common participants in the apoptotic cascade (BCL-2 and BAX) are present throughout human preimplantation development. In addition, the present study has shown that a proposed intermediate in the IGF-I survival pathway, BAD, is expressed mainly after compaction. Finally, the executors of cell death, active caspases, are present after compaction and are frequently associated with apoptotic nuclei. Together with our previous report that two morphological features of apoptosis, fragmenting nuclei and DNA, appear after compaction (Hardy et al., 2001), observations from the present study indicate that apoptosis is inhibited during early cleavage. However, the reasons for particular cells within the morula and blastocyst undergoing apoptosis are still unclear and the early signalling events that trigger an embryo cell to die are unknown.

The authors would like to thank the Wolfson IVF Unit. The authors are grateful for the confocal microscopy assistance of D. Ciantar.
