Follicular waves and circulating concentrations of gonadotrophins, inhibin and oestradiol during the anovulatory season in mares

F. X. Donadeu and O. J. Ginther

Department of Animal Health and Biomedical Sciences, University of Wisconsin, Madison, WI 53706, USA; and Eutheria Foundation, Cross Plains, WI 53528, USA

Introduction

Mares are seasonal breeders, with maximal ovulatory activity during long days (ovulatory season) and minimal activity during short days (anovulatory season). During the middle of the anovulatory season, only small (< 15 mm in diameter) follicles may be present. The follicles grow to increasingly larger mean diameters during the last 2–3 months of the anovulatory season or transitional period, culminating in the development of an ovulatory follicle (reviewed by Ginther, 1992). In transitional mares, one to several large (> 30 mm) anovulatory follicles may develop periodically preceding the development of the ovulatory follicle (Ginther, 1990; Watson et al., 2002). Follicular waves are defined as the synchronous development of a cohort of follicles (reviewed in Ginther, 1992). During the ovulatory season, waves are usually associated with the development of large (> 30 mm) dominant follicles (major waves), but waves may occur without a dominant follicle (minor waves). Major waves have been presumed to occur during the transition between the anovulatory and ovulatory seasons based on the periodic detection of large (> 30 mm) anovulatory follicles (Ginther, 1990; Watson et al., 2002). These studies have not demonstrated adequately that the large follicle developed from a cohort of follicles. In addition, it is not known whether the small follicles during the middle of the anovulatory season resulted from minor waves.

Differences in the proportion and type of pituitary gonadotrophs have been described between anovulatory and ovulatory mares (Eagle and Tortonese, 2000). However, pituitary FSH concentrations are not different between the anovulatory and ovulatory seasons (Silvia et al., 1986). Mean FSH concentrations (Freedman et al., 1979; Turner et al., 1979; Hines et al., 1991) and pulse amplitude (Hines et al., 1991) were high during the middle of the anovulatory season and declined during the last 60 days of the season with a more pronounced decline during the last 20 days (Freedman et al., 1979). During the gradual 60 day decline in mean FSH concentrations, the follicles grew to increasingly large mean diameters (Freedman et al., 1979). Surges in FSH are associated with the emergence of follicular waves during the ovulatory season (Ginther and Bergfelt, 1993) and have been detected during the early
development of large (> 30 mm) anovulatory follicles near the end of transition (Ginther, 1992; Watson et al., 2002). The occurrence of FSH surges and the temporal relationships between follicle development and FSH surges have not been reported for the middle of the anovulatory season. Clarification of the follicle–FSH relationships in anovulatory mares likely will require shorter intervals between evaluations and the development of common reference points for normalization among mares.

In contrast to FSH, mean pituitary (Silvia et al., 1986) and circulating (Oxender et al., 1977; Freedman et al., 1979; Fitzgerald et al., 1987; Alexander and Irvine, 1991) concentrations of LH are minimal during most of the anovulatory season and increase shortly before the first ovulation of the year. An increase in circulating LH pulse frequency and a decrease in pulse amplitude occur throughout the transition into the ovulatory season (Fitzgerald et al., 1987). Similar to LH, mean circulating oestradiol concentrations remain low during most of the anovulatory season and increase during the last stages of the transitional period in association with the development of large follicles (Oxender et al., 1977; Freedman et al., 1979; Seamans and Sharp, 1982) that have increased vascularity (Watson and Al-zi’abi, 2002) and steroidogenic competence (Davis and Sharp, 1991; Bogh et al., 2000).

The temporal relationships among the day-to-day changes in circulating inhibin concentrations and FSH concentrations and follicle diameter have been reported for the ovulatory season (Donadeu and Ginther, 2001; Bergfelt et al., 2001) but not within the various stages of the anovulatory season. In a recent study (Watson et al., 2002), mean plasma concentrations of inhibin A and inhibin isoforms containing pro- and -αC were higher during the development of large transitional follicles (25–40 mm) than during winter, when only small follicles were present. In stallions, inhibin concentrations were lowest during winter and highest during summer (Roser et al., 1994; Nagata et al., 1998).

The present study in mares was done to test the hypotheses that follicular waves, defined as emergence of a cohort of follicles, occur during the middle of the anovulatory season and during the transition into the ovulatory season and that the waves at all stages are temporally associated with changes in circulating concentrations of FSH. In addition, the day-to-day relationships among changes in follicle diameters and circulating concentrations of FSH, LH, total inhibin and oestradiol were characterized from the middle of the anovulatory season until the first ovulation of the year.

Materials and Methods

Experimental animals and follicles

Non-lactating pony mares (n = 8) of mixed breeding, aged 9–16 years, body weight 230–400 kg, were kept under natural light in an open shelter and outdoor paddock in the Northern Hemisphere (latitude, 43° N; WI). Mares were fed alfalfa and grass hay and had free access to water and mineralized salt. Ovaries were monitored transrectally once a day with an ultrasound scanner equipped with a 5 MHz linear-array transducer (Aloka SSD-500V; Aloka, Wallingford, CT), beginning on 29 January and continuing until the first ovulation of the year. At each scanning session, the number and diameter of follicles ≥ 10.0 mm in diameter were recorded, the diameter being estimated by comparison with the graduation marks on the scanner screen, and the six largest follicles were measured with electronic calipers by taking the mean width and length from a frozen image (Ginther, 1995).

Blood sampling and hormone assays

A jugular blood sample was collected daily from each mare for measurement of circulating hormone concentrations. Blood samples were immediately centrifuged at 1500 g for 16 min and the plasma fraction was separated and stored at −20°C. Plasma concentrations of FSH and LH were measured by double-antibody radioimmunoassays, as described for mares (Donadeu and Ginther, 2002). Intra-assay and interassay CVs were 12.4% and 13.4% for FSH and 7.8% and 5.5% for LH, respectively. Assay sensitivities were 1.4 ng FSH ml⁻¹ and 0.1 ng LH ml⁻¹. For all hormones, sensitivity was calculated by subtracting two standard deviations from the mean maximum percentage binding and averaging over all assays.

Concentrations of total (immunoreactive) inhibin were measured in plasma by a double-antibody radioimmunoassay kit (Institute of Reproduction and Development, Monash Medical Center, Clayton), as described by Donadeu and Ginther (2001). The antibody recognizes dimeric inhibin forms, as well as free α-subunit forms (Roser et al., 1994). Intra-assay and interassay CVs were 9.1% and 15.0%, respectively, and the sensitivity was 5.8 ng ml⁻¹.

Plasma concentrations of oestradiol were measured by a double-antibody radioimmunoassay kit (Double Antibody Estradiol, Diagnostic Products Corporation, Los Angeles) after extracting the samples with ether, as described for mare samples (Gastal et al., 1999). Intra-assay and interassay CVs were 14.8% and 17.5%, respectively, and the sensitivity was 0.03 pg ml⁻¹.

Follicle and hormone endpoints

For analyses involving measurements over time, the endpoints for largest follicle(s) and number of follicles refer to follicle(s) for each day without consideration of day-to-day identity. Follicular waves were detected by an adaptation of a mathematical method described in mares by Ginther and Bergfelt (1992a). The diameters of the second to sixth largest follicles were statistically analysed within each mare. Data from the largest follicle and from any follicle reaching > 28 mm were excluded to minimize the variation within days (Ginther and Bergfelt, 1992a). A
significant increase in the mean diameter of the second to sixth largest follicles was used to identify the beginning of a follicular wave. The day of emergence of a wave was defined by the beginning of the significant increase.

Surges in FSH and fluctuations in oestradiol in daily circulating concentrations within each mare were differentiated from variation due to extraneous factors (variation in sampling or assaying technique), as described by Fitzgerald et al. (1985) in mares. The CV of the values composing the ascending and descending portions of the suspected surge or fluctuation had to be at least three times higher than the mean intra-assay CV. In addition, a given surge or fluctuation had to include values from at least 2 days. The highest value associated with an identified surge or fluctuation was defined as a peak. The amplitude of a surge or fluctuation was defined as the difference between concentrations at the peak and concentrations at the preceding nadir.

Inspection of follicle characteristics for individual mares indicated the presence of three distinct periods of follicle activity during the second-half of the anovulatory season in each mare. Therefore, data for individual mares were partitioned into a mid-anovulatory period, a transitional period, and a preovulatory period. The mid-anovulatory period was defined by a diameter of the largest follicle of < 21.0 mm. The beginning of the transitional period was defined by the first increase in the diameter of the largest follicle that resulted in a ≥ 21.0 mm follicle. The day the ovulatory follicle reached ≥ 21.0 mm, as determined retrospectively, was used to separate the transitional and preovulatory periods.

Changes in follicle and hormone endpoints during the mid-anovulatory and transitional periods were studied by analysing data from 34 days before to 34 days after the beginning of the transitional period. This interval was chosen based on the maximum availability of data from the mares. Follicle and hormone endpoints were also analysed from 4 days before to 10 days after the beginning of the preovulatory period. The relationships between follicular waves and circulating hormone concentrations were compared for identified waves during the mid-anovulatory period, beginning of the transitional period, and middle of the transitional period. In mares with multiple waves during the mid-anovulatory period, the last wave during the period was used for analysis. In each case, data were normalized to the beginning of waves, using data from 7 days before to 5 days after wave emergence. In addition, the relationships between identified FSH surges and follicle activity were compared between the mid-anovulatory and transitional periods. This was done by analysing the changes in mean diameter of the second to sixth largest follicles and in the number of follicles ≥ 15.0 mm in diameter relative to an FSH peak for identified FSH peaks that were central to each of the two periods. Within each mare the changes in the two follicle endpoints were calculated by subtracting the value on the day of the FSH peak from all other values. Data from 1 day before to 3 days after the peak were used. Means for single-point endpoints were compared among the mid-anovulatory, transitional and preovulatory periods or among waves occurring during the mid-anovulatory and transitional periods. The mean for each period or wave was determined for each individual mare and the degrees of freedom used in the comparisons were based on the number of mares.

**Statistical analyses**

Data for each end point were tested for normality with a Kolmogorov–Smirnov test (SAS Institute Inc., 1989) and normalized by log-transformation when the probability level (P) was P < 0.01. Data were then analysed by the SAS MIXED procedure (SAS Institute Inc., 1995) using the animal as the random term and accounting for the autocorrelation among samples taken over time. For the analysis of sequential data involving different periods, the animal within period was used as the random term. Main effects of day, period and the interaction were determined. Tukey’s tests were used in all statistical analyses for comparisons among means. Significance was considered at P < 0.05, whereas probabilities from > 0.05 to < 0.1 were considered as approaching significance.

**Results**

**Follicular periods**

The duration of the interval from 29 January to the first ovulation of the year was 69, 77, 82, 85, 86, 89, 111 and 122 days in the eight mares (mean, 90.1 ± 6.2 days). Mean date of ovulation was 28 April. Follicle and hormone profiles are shown for three individual mares, including defined periods and identified waves (Fig. 1). The maximal diameter of the largest follicle at any day during the mid-anovulatory period ranged from 17.8 to 20.8 mm in individual mares. The transitional period began 31–93 days before ovulation (mean, 51.5 ± 7.3 days). During the transitional period, an anovulatory follicle reached ≥ 30 mm in diameter in three of eight mares. In the remaining five mares, the largest follicle during the transitional period was 22.4 to 28.9 mm. The ovulatory follicle reached ≥ 21.0 mm (beginning of the preovulatory period) 6–14 days (mean, 10.1 ± 0.8 days) before the first ovulation of the year.

Mean follicle and hormone profiles from 34 days before to 34 days after the beginning of the transitional period and for 4 days before to 10 days after the beginning of the preovulatory period are shown (Fig. 2). The mean number of follicles > 15.0 mm diameter increased (P < 0.05) over the first 8 days of the transitional period and decreased (P < 0.05) during the preovulatory period. The mean diameter of the largest follicle increased (P < 0.0001) during the first 8 days of the transitional period; a further increase (P < 0.0001) occurred during the preovulatory period, after the ovulatory follicle had become the largest follicle.

No effect of day (P > 0.1) was found for FSH
concentrations for the 34 days before and after the beginning of the transitional period (Fig. 2). However, FSH concentrations decreased ($P < 0.05$) from 2 days before to 3 days after the beginning of the preovulatory period and then remained low until ovulation. Surges in circulating FSH were identified in all mares during the mid-anovulatory period (one to three surges per mare), in seven mares during the transitional period (one to five surges) and in only two
mares during the preovulatory period (one surge). Of all identified FSH surges, 69% were not associated with statistically identified waves, as indicated by an interval between the FSH peak and the emergence of a wave of >4 days. An effect of day ($P < 0.001$) for circulating LH concentrations resulted from a slight progressive increase in mean concentrations during the mid-anovulatory and transitional periods (Fig. 2); LH concentrations remained...
below 2 ng LH ml\(^{-1}\) during the two periods in each mare. LH increased (\(P < 0.05\)) during 4–10 days after the beginning of the preovulatory period.

There was an increase (\(P < 0.0001\)) in circulating total inhibin concentrations from 5 days before to 6 days after the beginning of the transitional period (Fig. 2). An overall day effect for circulating oestradiol concentrations was not found during the mid-anovulatory and transitional periods. However, sporadic small fluctuations in circulating oestradiol (Table 1) were identified statistically in all mares during the two periods. Mean oestradiol concentrations increased (\(P < 0.05\)) during 2–8 days after the beginning of
the preovulatory period. Single-point follicle and hormone means and the results of statistical analyses for the mid-anovulatory, transitional and preovulatory periods are shown (Table 1).

**Follicular waves**

Two to five follicular waves, as indicated by a significant increase in the mean diameter of the second to sixth largest follicles (Fig. 1), were detected in each mare during the study. During the mid-anovulatory period, two mares had two and three identified waves, five mares had one identified wave, and one mare had no identified wave. An identified wave at the beginning of the transitional period occurred in all mares, in temporal association with the increase in mean diameter of the largest follicle and the number of follicles > 15 mm in diameter (Fig. 2). During the remaining transitional period, one wave was detected in each of four mares and two waves were detected in one mare. A wave was statistically identified at the end of the transitional period in temporal association with a growing ovulatory follicle in only one of eight mares.

Results of comparing follicular waves occurring during the mid-anovulatory period and at the beginning and middle of the transitional period are shown (Table 2; Fig. 3). Mean diameter of the second to sixth largest follicles was larger (P < 0.05) for waves during the middle of the transitional period than for waves during the mid-

<sup>a,b</sup>Means within an endpoint with different superscripts are significantly different (P < 0.05).
anovulatory period on each day during days 0–5 after wave emergence (Fig. 3). Averaged over all periods, FSH concentrations increased \((P < 0.05)\) and then decreased \((P < 0.05)\) during 6 days before to 5 days after wave emergence. However, there was no effect of period or a period by day interaction for FSH concentrations associated with waves. An increase \((P < 0.05)\) in total inhibin concentrations occurred from 2 days before to 2 days after emergence of waves for the three periods combined. Total inhibin concentrations were higher \((P < 0.05)\) for waves during the middle of the transitional period than for waves during the mid-anovulatory period and beginning of the transitional period at each day from 7 days before to 1 day after wave emergence, except on the day of wave emergence. Concentrations were higher \((P < 0.05)\) at day 4 after wave emergence for waves during the middle of the transitional period than for waves during the mid-anovulatory period. No significant effect was found for concentrations of oestradiol or LH relative to wave emergence.

Averaged over the mid-anovulatory and transitional periods, there were increases in the number of follicles \(\geq 15.0\) mm in diameter \((P < 0.05)\) and diameter of the second to sixth largest follicles \((P < 0.05)\) after an identified FSH peak (Fig. 4). Circulating FSH concentrations from 1 day before to 3 days after the peak of an FSH surge were not significantly different between the two periods.

**Discussion**

The presence of a mid-anovulatory period (largest follicle \(< 21\) mm in diameter) in each mare from the beginning of the study (29 January) to an average of 8 March or 52 days before the first ovulation of the year is consistent with the report (Turner et al., 1979) that follicles \(> 20\) mm in diameter were not detected in ponies until an average of mid-March or about 60 days before the onset of the ovulatory season. An increase in the diameter of the largest follicle and numbers of follicles \(\geq 15\) mm in diameter occurred during the first 8 days of the transitional period and represented an identified follicular wave in all mares. This distinct increase and subsequent maintenance of enhanced follicular activity allowed normalization of the data using the increase as a reference point. This characteristic of the anovulatory season has not been reported previously, and the 8 days increase contrasts with the reported progressive increases in mean follicle diameters and numbers during the 60–75 days before the first ovulation of the year in ponies (Freedman et al., 1979; Turner et al., 1979) and horses (Carnevale et al., 1997). As the short-term increases in follicle diameter and numbers at the beginning of the transitional period occurred at a variable time before the first ovulation in individual mares, the increases probably would have been masked in the previous studies by the normalization of data to the first ovulation of the year. In the present study, three of the eight mares developed a large \(\geq 30\) mm anovulatory follicle before developing an ovulatory follicle. In previous studies, seven of 15 (Ginther, 1990) and nine of ten (Watson et al., 2002) mares developed one to three large anovulatory follicles during the transition into the ovulatory season. The reason for the apparent lower frequency of such mares in the present study than in the study by Watson et al. (2002) is not known.

The results of the present study support the hypothesis that follicular waves develop throughout the later half of the anovulatory season in mares. This hypothesis has not been tested previously in mares, but waves have been reported during the anovulatory season in ewes (Bartlewski et al., 1999; Evans et al., 2001). Minor waves developed in all mares during the mid-anovulatory period and the transitional period, except for mare C which had a short anovulatory period. A major wave (largest follicle \(\geq 30\) mm) developed in three mares during the transitional period. A background of larger follicles during the transitional period than during the mid-anovulatory period resulted in the detection of wave emergence at a larger mean diameter during the middle of the transitional period than during the mid-anovulatory period. There was agreement between statistically identified waves and an apparent synchronous growth of several individual follicles during all periods of the current study. However, inspection of data for individual follicles also indicated that some waves were not detected by significant increases in the mean diameter of the second to sixth largest follicles. A statistical wave seemed associated with emergence of the ovulatory follicle in only one of eight mares. In three of the remaining mares, an apparent wave was detected by inspection of the profiles of the six largest follicles. In the other mares, the presence of a wave in association with the emergence of the ovulatory follicle was not apparent by visual inspection. The obscurement of waves seemed attributable primarily to the masking effect of regressing follicles from a previous minor or major wave. Failure to identify waves does not diminish the objectivity of the study because only the statistically identified waves were used to study hormonal changes associated with waves. Although follicles developed in clusters or waves during the three periods, the development of other follicles in isolation has not been eliminated by this study.

The hypothesis of a temporal association between FSH increases and follicular waves during the anovulatory season was supported and was demonstrated both by normalizing FSH data to wave emergence and by normalizing follicle data to FSH peaks. A temporal relationship between FSH surges and the emergence of a cohort of follicles (wave) during the anovulatory season has not been reported previously; however, FSH surges have been reported, anecdotally, in temporal association with the emergence of large anovulatory follicles near the end of transition (Ginther, 1992; Watson et al., 2002). A similar relationship between increases in FSH concentrations and the emergence of follicular waves occurs during the
Follicular waves in anovulatory mares

883

ovulatory season (Ginther and Bergfelt, 1993) and pregnancy (Ginther and Bergfelt, 1992b) in mares, and during the anovulatory season in ewes (Evans et al., 2001). However, FSH surges were also identified in the present study that were not associated with waves, in agreement with recent reports in mares (Watson et al., 2002) and ewes (Evans et al., 2001). In the present study, the changes in FSH concentrations associated with follicular waves were not different among the mid-anovulatory period, beginning of the transitional period, and middle of the transitional period. The increase in follicle diameters that distinctly separated the mid-anovulatory and transitional periods, therefore, is not attributable to differences in the FSH surges. Changes in follicular responsiveness to the wave-stimulating FSH may have been involved. In this regard, changes in concentrations of follicular-fluid factors may modulate the sensitivity of follicles to FSH during the ovulatory season (Sanford et al., 2002). An increase in FSH receptor expression in temporal association with gonadal recrudescence at the end of the non-breeding season (Sanford et al., 2002) and an increase in the half-life with gonadal recrudescence at the end of the non-breeding season (Donadeu and Ginther, 2002). An increase in follicle diameters that distinctly separated the mid-anovulatory and transitional periods, therefore, is not attributable to differences in the FSH surges. Changes in follicular responsiveness to the wave-stimulating FSH may have been involved. In this regard, changes in concentrations of follicular-fluid factors may modulate the sensitivity of follicles to FSH during the ovulatory season (Sanford et al., 2002). An increase in FSH receptor expression in temporal association with gonadal recrudescence at the end of the non-breeding season (Sanford et al., 2002) and an increase in the half-life of pituitary FSH isoforms from the anovulatory to the ovulatory season (Moore et al., 2000) have been described in sheep, and alternatively may be involved in an increase in the follicle response to gonadotrophins at the beginning of the transitional period in mares.

The temporal relationships between follicular waves and changing inhibin concentrations have apparently not been reported previously for anovulatory mares. In the present study, an increase in circulating concentrations of total inhibin encompassed the development of follicular waves during the mid-anovulatory and transitional periods. In addition, total inhibin concentrations increased with the increase in follicle diameters and numbers at the beginning of the transitional period and concentrations were highest during the preovulatory period. Consistent with the present results, mean plasma concentrations of inhibin A and pro-and αC inhibins were lowest during the middle of the anovulatory season, higher during the stage of large anovulatory follicles (25–40 mm) and highest when an ovulatory follicle was present (Watson et al., 2002). Thus, the conclusions were similar when based on assay of total inhibin (the present study) as when based on assay of individual inhibin isoforms (Watson et al., 2002). A positive relationship between follicle diameters and numbers and circulating total inhibin concentrations has also been reported during the ovulatory season (Donadeu and Ginther, 2001). A role for inhibin in the suppression of circulating FSH in seasonally anovulatory mares was suggested by the temporal relationships between an increase in circulating total inhibin and a decrease in FSH concentrations during wave development and is similar to results for the ovulatory season (Bergfelt et al., 2001; Donadeu and Ginther, 2001). A role for a follicular factor, presumably inhibin, in the suppression of FSH has been suggested, based on progressive decreases in FSH pulse amplitude and mean daily circulating FSH concentrations (Hines et al., 1991) and on GnRH-induced pituitary FSH secretion (Silvia et al., 1987) during the transition into the ovulatory season. In the present study, a decrease (not significant) in mean daily circulating FSH occurred throughout the transitional period in temporal association with the high circulating concentrations of inhibin. Maximal FSH suppression during the preovulatory period presumably was accounted for by the high circulating inhibin, as well as oestradiol (Gastal et al., 1999).

Circulating oestradiol concentrations were low during the mid-anovulatory and transitional periods compared with the first preovulatory period, in agreement with previous reports (Oxender et al., 1977; Seams et al., 1982), and did not increase with follicular wave emergence during the mid-anovulatory and transitional periods. Watson et al. (2002), however, reported a small increase in circulating oestradiol during the growth of large follicles (25–40 mm) in late transitional mares. Large (> 30 mm) anovulatory follicles produce limited oestradiol and this production increases at the end of the transition into the ovulatory season (Davis and Sharp, 1991). Watson and Ali-zab’i (2002) concluded that the low steroidogenic capacity of anovulatory follicles is probably due to poor vascularity and development of the theca layer. In the present study, subtle statistical fluctuations in circulating concentrations of oestradiol were detected sporadically during the mid-anovulatory and transitional periods, and the fluctuations often did not appear to be associated with growth of follicles. Oestradiol concentrations associated with these fluctuations may be related to the reported occurrence of unseasonal oestrus during the anovulatory season in intact mares (Ginther, 1974; Asa et al., 1980a; Ginther, 1990) and ovariectomized mares (Asa et al., 1980a). A role for adrenal steroids in causing unseasonal oestrous behaviour in mares has been suggested (Asa et al., 1980b; Pope et al., 1995). On the basis of these results, the sporadic and slight fluctuations in oestradiol may not have been of ovarian origin.

A slight increase in mean circulating LH concentrations over the mid-anovulatory and transitional periods may reflect a progressive increase in LH pulse frequency during the last 2 months of the anovulatory season in mares (Fitzgerald et al., 1987). Pituitary LH concentrations gradually increase during the transition into the ovulatory season (Silvia et al., 1986) and circulating LH concentrations apparently reflect pituitary content in transitional mares (Silvia et al., 1987). Despite the reports of a gradual increase, circulating LH concentrations associated with follicular wave emergence were not different between the mid-anovulatory and transitional periods in the present study. Further study is needed to determine whether an increase in LH accounts for the increase in follicle growth associated with a follicular wave at the beginning of the transitional period. It was suggested by Sharp et al. (1991, 2001) that increasing circulating oestradiol concentrations at the end of the anovulatory season act to stimulate pituitary LH synthesis and secretion resulting in an ovulatory LH surge in mares. This suggestion
is consistent with the present results of a preovulatory increase in circulating LH concentrations following an increase in circulating oestradiol.

In summary, the results of the present study indicate that follicular waves occur even during the limited follicular activity of the mid-anovulatory period (largest follicle < 21 mm). Temporal relationships indicate that follicular waves were stimulated by increases in circulating FSH concentrations during the mid-anovulatory and transitional periods. In addition, the growing follicles produced inhibin, which would account, at least partly, for the subsequent suppression of FSH secretion. A distinct increase in follicle diameter associated with a follicular wave occurred at the beginning of the transitional period. However, the FSH surges associated with waves were similar during the mid-anovulatory and transitional periods, indicating that factors other than the nature of FSH surges account for the increased follicle responsiveness at the beginning of the transitional period.

The authors thank J. A. O'Sullivan for technical assistance, A. F. Parlow from the National Hormone and Pituitary Program for gonadotrophin radioimmunoassay reagents, and D. R. Bergfelt for manuscript review.
