After parturition, the uterus undergoes marked remodelling during involution; however, little is known of the hormonal, cellular and molecular mechanisms that regulate this process. The working hypothesis used in this study is that return of the ovine uterus to a non-pregnant state involves termination of a hormonal servomechanism that regulates endometrial gland morphogenesis and function during pregnancy. Suffolk ewes were ovariohysterectomized on postpartum days 1, 7, 14 or 28. Serum concentrations of oestradiol were high at parturition, declined to postpartum day 4, peaked on postpartum day 6, and then declined and remained low thereafter. Progesterone was undetectable in plasma from ewes post partum. Uterine wet mass and horn length decreased after postpartum day 1, but ovarian mass did not change. Residual placental cotyledons were present in the maternal caruncles on postpartum days 1 and 7 and were extruded by postpartum day 14 as plaques that were resorbed by postpartum day 28. The width of the total endometrium, stratum compactum, stratum spongiosum and myometrium, as well as endometrial gland density, decreased after parturition. Most apoptotic cells in the involuting uterus were large, vacuolated and located between the endometrial glandular epithelial cells on postpartum days 1 and 7. Immuno-fluorescence analyses identified both T and B cells within the glandular epithelium on postpartum day 1. Cell proliferation was detected in the luminal epithelium and glandular epithelium on postpartum days 1 and 7. On postpartum day 1, expression of oestrogen receptor alpha (ERα) was not detected in luminal epithelium and was low in glandular epithelium, but ERα was present in epithelia thereafter. Progesterone receptor (PR) protein was not detected in endometrial epithelia on postpartum day 1, but was detected in the glandular epithelium thereafter. Between postpartum days 1 and 7, ERα and PR protein increased substantially in the endometrial glandular epithelium. On postpartum days 1–28, abundant expression of oxytocin receptor mRNA was detected in endometrial luminal epithelium and superficial to the middle glandular epithelium. Prolactin receptor (PRLR) mRNA was detected in glandular epithelium on all postpartum days, whereas mRNA for uterine milk protein (UTMP), an index of secretory capacity of glandular epithelium, was present only on postpartum day 1. Collectively, these results indicate that uterine involution in ewes involves remodelling of both caruncular and intercaruncular areas of the uterine wall and termination of differentiated uterine gland functions characteristic of pregnancy.

Introduction

After parturition, the uterus undergoes involution, a process defined as the retrograde changes in female reproductive organs that return the uterus to a cyclic or non-pregnant size (for review, see Kiracofe, 1980). Uterine involution in cattle is complete when the uterine horns return to the position, size and tone of a non-pregnant or cyclic animal (Casida et al., 1968). A variety of factors, such as parity (Rasbeck, 1950; Marion and Gier, 1968), lactational status (Willbank and Cook, 1958; Casida et al., 1968; Riesen, 1968), nutrition (Willbank et al., 1962; Dunn et al., 1969), breed and season, influence the time to complete uterine involution. The process of uterine involution in cattle and sheep involves an overall size reduction, loss of cotyledonary tissue, and tissue repair (Gier and Marion, 1968; van Wyk et al., 1972a,b; O’Shea and Wright, 1984). During the first week after parturition, the placental vasculature responsible for haematotrophic nutrition of the fetus degenerates. As a result, the uterine lumen is filled with lochia, a thick brown substance produced by autolysis of red blood cells (van Wyk et al., 1972a). This period is also characterized by dissolution of the fetal and maternal layers of the placenta and expulsion of the remaining fetal cotyledonary placenta. During the second week post partum, brown necrotic plaques are released from the involuting caruncles and fill the uterine lumen.
(van Wyk et al., 1972a). Re-epithelialization of the caruncles occurs during the third and fourth weeks post partum (O’Shea and Wright, 1984) concurrent with decreases in uterine size, mass and horn length (van Wyk et al., 1972b). However, the histoarchitectural changes in the intercaruncular endometrium after parturition have not been reported.

During gestation, endometrial gland morphogenesis and differentiation occurs in the intercaruncular endometrium to provide increasing amounts of secreted histotroph (Stewart et al., 2000). These secretions are absorbed by areolae within the interplacentomal placenta for nutrition of the fetus (Amoroso, 1952). During pregnancy, uterine glands undergo hyperplasia between day 15 and day 50, followed by hypertrophy that precedes maximal secretion of histotroph (Wimsatt, 1950; Moffatt et al., 1987; Stewart et al., 2000). Endometrial gland morphogenesis and differentiated secretory function during gestation appear to be regulated by a hormonal servomechanism involving the sequential effects of oestrogen, progesterone, ovine placental lactogen (PL) and ovine placental growth hormone (GH) (Spencer et al., 1999; Gray et al., 2001; Spencer and Bazer, 2002). During oestrus and metoestrus, oestrogen acts via oestrogen receptor alpha (ERα) to increase expression of progesterone receptor (PR) in the endometrial epithelia (Spencer and Bazer, 1995; Spencer et al., 1996, 1999). However, continual exposure of the endometrium to progesterone downregulates PR expression in the luminal epithelium by day 13 and in the glandular epithelium by day 15 (Spencer and Bazer, 1995; Spencer et al., 1999). The absence of PR allows for oestrogen to increase ERα and then oxytocin receptor (OTR) gene expression in the luminal epithium and superficial glandular epithelium (Spencer et al., 1996). After establishment of pregnancy, expression of ERα and PR genes are notably absent in the endometrial epithelia (Spencer and Bazer, 1995; T. E. Spencer, unpublished). The effects of progesterone to induce expression of secretory proteins, such as uterine milk proteins (UTMP) and osteopontin, in the endometrial glands are due to the negative autoregulatory effects of progesterone on epithelial PR expression (Spencer et al., 1999; Johnson et al., 2000; Spencer and Bazer, 2002). The UTMPs are members of the serpin family of serine proteinase inhibitors (Ing and Roberts, 1989) and are excellent markers of endometrial gland differentiated function, because they are the most abundant secreted proteins in the ovine uterus (Bazer et al., 1979; Moffat et al., 1987; Stewart et al., 2000). Intruterine infusion of ovine placental lactogen into the uterus of ewes treated with progesterone and interferon tau (iFN-τ) increases endometrial gland proliferation and production of UTMP (Spencer et al., 1999). The effects of placental lactogen on endometrial glandular epithelium are predominantly mediated by homodimerization of the prolactin receptor (PRLR). The PRLR is expressed exclusively in the endometrial glandular epithelium during pregnancy (Stewart et al., 2000).

The working hypothesis used in this study is that uterine involution involves termination of the hormonal servomechanism regulating uterine gland morphogenesis and secretory function. Therefore, processes involved in return of the uterine glands to a non-pregnant state may involve alterations in cell type specific expression of hormone receptors as well as cell death and proliferation. Consequently, this study determined the effects of postpartum day on: (1) circulating concentrations of oestradiol and progesterone; (2) ovarian and uterine histoarchitecture; and (3) spatial alterations in endometrial cell proliferation, apoptosis and expression of ERα, PR, OTR, PRLR and UTMP in the intercaruncular endometrium.

Materials and Methods

Animals

Experimental and surgical procedures were in compliance with the Guide for Care and Use of Agriculture Animals and were approved by the Institutional Agricultural Animal Care and Use Committee of Texas A&M University. Multiparous Suffolk ewes (n = 17), 5–8 years of age, were mated with rams of proven fertility, and pregnancy was determined by transabdominal ultrasonography. Ewes were pastured during most of gestation and fed alfalfa hay ad libitum and supplemented with whole corn during the last month of gestation. Ewes were checked twice a day for signs of labour or parturition. The number of lambs born to each ewe was recorded at parturition. Lambs were observed twice a day to ensure that they were nursing ewes.

Experimental design and tissue collection

Blood samples were collected from ewes bled daily via jugular venepuncture with Vacutainer evacuated blood collection tubes with sodium heparin (for plasma) or no additive (for serum) (Becton-Dickinson, Franklin Lakes, NJ) beginning at parturition (day of birth or postpartum day 0) to ovariohysterectomy. Plasma or serum was isolated from blood samples by centrifugation at 1500 g for 10 min and stored at −20°C.

Ewes were assigned randomly to undergo ovariohysterectomy on postpartum day 1, 7, 14 or 28 (n = 4–5 ewes per day). At surgery, ovarian mass, uterine mass and uterine horn length were measured. Ovaries were fixed in freshly prepared 4% paraformaldehyde in PBS (pH 7.2). Residual placentomal or caruncular and intercaruncular areas of the uterine wall were dissected from the uteri of ewes on postpartum days 1, 7 or 14, and sections (of about 1 cm) fixed in 4% paraformaldehyde. On postpartum day 28, sections from the mid-portion of each uterine horn were fixed in...
4% paraformaldehyde. After 24 h, fixed tissues were dehydrated through a graded series of ethanol solutions and embedded in Paraplast Plus (Oxford Labware, St Louis, MO) for histological analyses. Several sections of the uterine horns were also embedded in optimal cutting temperature (OCT) compound (Miles, Oneota, NY), snap-frozen in liquid nitrogen, and stored at –80°C.

Steroid radioimmunoassay

Progesterone concentrations in plasma samples were determined in a single assay using an active progesterone radioimmunoassay kit (Diagnostic Systems Laboratories, Inc., Webster, TX) as described by Gray et al. (2000a). Assay sensitivity was 0.1 ng progesterone ml\(^{-1}\), and the intra-assay coefficient of variation was 5.2%. Serum samples were extracted with ethyl ether. Oestradiol concentrations in serum extracts were determined using an active oestrogen radioimmunoassay kit (Diagnostic Systems Laboratories, Inc.) according to the manufacturer's recommendations. Assay sensitivity was 1 pg oestradiol ml\(^{-1}\), and the intra-assay coefficient of variation was 10%. For both steroid assays, results were calculated using the AssayZap program (Biosoft, Ferguson, MO).

Histology and morphometry

Sections (5 μm) of paraffin wax-embedded tissues were stained with haematoxylin and eosin or Masson's trichrome stain as described by Gray et al. (2002). For morphometry, sections (n = 5) of the uterus from each ewe were stained with haematoxylin and eosin, photomicrographed, and images were analysed using Scion Image software (Scion Corporation, Frederick, MD). Measurements were standardized using the image of a stage micrometer at the same magnification. In the intercaruncular endometrium, total endometrial depth, width of stratum compactum and stratum spongiosum, gland cross-section width, total myometrial depth, and width of inner circular and outer longitudinal layers were measured using computer-assisted image analysis software. Morphometrical width determinations were made from multiple measurements (n = 5–9) of each uterus.

Immunohistochemistry

Immunoreactive proliferating cell nuclear antigen (PCNA), ER\(\alpha\) and PR proteins were localized in uterine tissue sections (5 μm) using specific antibodies and a super ABC mouse/rat IgG kit (Biomedica, Foster City, CA) as described by Gray et al. (2000a,b). Mouse antibody to PCNA was purchased from DAKO Corporation (Carpinteria, CA). Rat antibody to human ER\(\alpha\) (H222) was provided by G. Greene (Abbott Laboratories, Chicago, IL). Mouse monoclonal antibody to the human PR (MA1-411) was purchased from Affinity Bioreagents (Golden, CO). PCNA antibody was used at a final concentration of 1 μg ml\(^{-1}\), and ER\(\alpha\) and PR antibodies were both used at a final concentration of 5 μg ml\(^{-1}\). Negative controls included substitution of the primary antibody with purified mouse IgG (PCNA and PR) or rat IgG (ER\(\alpha\)).

Immunofluorescence analyses

Mouse monoclonal antibodies used for immunocytochemical identification of interepithelial immune cells were provided by W. Davis (Washington State University) and included CACT + 80C specific for CD8, GC1A specific for CD4, GS5A specific for B cells and naïve T cells, BAQ44A specific for BAQ44a-defined molecule expressed on B cells, DH59B specific for CD172a expressed on monocytes–macrophages, dendritic cells and macrophages, and BA7A1 and BAQ44A specific for the γδ T-cell surface markers WC1-N1 and WC1-N2, respectively. Proteins were localized in frozen uterine tissue sections (8–10 μm) by immunofluorescence staining as described by Johnson et al. (1999). Frozen sections were fixed in methanol at –20°C, permeabilized with 0.3% Tween 20 in 0.02 mol PBS1\(^{-1}\), blocked in 10% normal goat serum, and incubated overnight at 4°C with 12 μg primary antibody ml\(^{-1}\). Immunoreactive protein was then detected using a fluorescein-conjugated goat anti-mouse IgG (Zymed, San Francisco, CA). Coverslips were placed over a layer of Prolong antifade mounting reagent (Molecular Probes, Eugene, OR).

In situ apoptosis staining

Paraffin wax-embedded sections of uterine wall (5 μm in thickness) from postpartum ewes were evaluated using the TACS 2 TdT in situ apoptosis kit from Trevigen (Gaithersberg, MD) following the manufacturer’s directions. Positive controls were tissues that were digested with nuclease to expose DNA ends. Labelling was visualized using diaminobenzidine as a chromogen, and sections were counterstained with methyl green.

In situ hybridization

The OTR, PRLR and UTMP mRNAs were localized in uterine tissue sections by in situ hybridization as described by Spencer et al. (1999), Gray et al. (2000a) and Stewart et al. (2000). Uterine sections (5 μm) were deparaffinized, rehydrated, deproteinized and hybridized with radiolabelled antisense or sense ovine OTR (Riley et al., 1996), bovine PRLR (Scott et al., 1992) or ovine UTMP (Stewart et al., 2000) cRNAs generated from linearized plasmid templates using in vitro transcription with [α-\(^{35}\)S]UTP. Autoradiographs of slides were prepared using Kodak NTB-2 liquid.
photographic emulsion. Slides were stored at 4°C for 1–2 weeks, developed in Kodak D-19 developer, counterstained with Harris’ modified haematoxylin (Fisher Scientific, Fairlawn, NJ), dehydrated through a graded series of alcohols to xylene, and coverslips were applied.

Photomicroscopy

Photomicrographs were taken using a Nikon Eclipse E1000 photomicroscope (Nikon Instruments, Inc., Melville, NY). Digital images were captured using a Nikon DXM 1200 digital camera and assembled using Adobe Photoshop 5.5 (Adobe Systems, Seattle, WA). For immunofluorescence analyses, representative fluorescence images of cross-sections exhibiting immunological crossreactivity were recorded using a Zeiss Axioplan microscope (Carl Zeiss, Thornwood, NY) equipped with a Hamamatsu chilled 3CCD colour camera (Hamamatsu, Japan) using Photoshop 5.0 (Adobe Systems) image capture software.

Statistical analyses

Data were subjected to least-squares ANOVA using the general linear models procedure of the statistical analysis system (SAS, 2000). For uterine mass and length measurements, the number of suckling lambs was used as a covariate in statistical models. All values were log-transformed to alleviate heterogeneity of error variance. Statistical models for analysis of morphometry data included main effects of postpartum day, ewe within postpartum day, tissue section, and microscopic field within tissue section, and the appropriate interactions. Initial analyses indicated that uterine wall location, tissue section and microscopic field within section were not significant sources of variation. Data are presented as least-square means (LSM) with pooled standard errors (SE).

Results

Circulating concentrations of progesterone and oestradiol

Concentrations of circulating oestradiol in serum changed with postpartum day \((P < 0.08\), fifth order effect of day). Serum concentrations of oestradiol were high at parturition, declined to postpartum day 4, peaked on postpartum day 6 (65 pg oestradiol ml\(^{-1}\)), and then declined to an average of 8 pg oestradiol ml\(^{-1}\) thereafter (data not shown). Plasma concentrations of progesterone were below detectable limits of the assay and not affected \((P = 0.65)\) by postpartum day (data not shown).

Gross observations and measurements

Each postpartum ewe maintained one or two suckling lambs. The ovaries of all ewes contained antral follicles at various stages of development and one or more corpora lutea (data not shown). Ovarian mass was not affected \((P = 0.262)\) by postpartum day (data not shown).

As expected, uterine mass \((P < 0.01\), quadratic) and uterine horn length \((P < 0.01\), quadratic) decreased between postpartum days 1 and 28 (Table 1). Gross anatomical changes in the involuting ovine uterus are illustrated (Fig. 1). A thick, dark lochia was present in the uterine lumen on postpartum days 1, 7 and 14, but was completely absent on postpartum day 28. On postpartum days 1 and 7, the residual placentomes or caruncles were distended and contained dark brown plaques, which were probably a combination of residual placental cotyledonary tissue and haemolysed blood. By postpartum day 14, these plaques were no longer attached to the uterus, but were free within the uterine lumen. By postpartum day 28, no plaques remained in the uterine lumen.

Histoarchitecture and morphometry

The histoarchitectural changes in the uterine wall are shown (Fig. 2), and morphometrical analyses of the intercaruncular endometrium are summarized (Table 1). In the intercaruncular areas of the uterus (Fig. 2), the width of the endometrium and myometrium was maximal on postpartum day 1. The endometrium contained enlarged endometrial glands and expanded stroma with little discernable extracellular matrix (ECM). Large, vacuous, nucleated cells were present within or between the endometrial glandular epithelium cells. The entire intercaruncular area contained many folds. On postpartum day 7, the endometrium was less folded with a noticeably ruffled luminal epithelium. Endometrial width was lower with an apparent reduction in extracellular space between cells in the stroma and distance between endometrial glands. A marked increase in extracellular matrix (ECM) staining was observed in the stroma. On postpartum day 14, the width of the endometrium and myometrium reached a minimum. Uterine glands appeared more organized and smaller than on postpartum day 7. The intercaruncular endometrium contained less folding, and the luminal epithelium was less ruffled in appearance. By postpartum day 28, the endometrium was histoarchitecturally similar to that of non-pregnant ewes. The luminal epithelium was noticeably less ruffled and less columnar. Although endometrial gland diameter reached a minimum on postpartum day 14, total endometrial and myometrial width increased slightly from postpartum day 14 to postpartum day 28.

On postpartum days 1 and 7, the residual placentomes or caruncles contained a combination of residual...

Data are presented as least-square means with overall pooled standard errors generated by ANOVA.

Fig. 1. Gross structure of the ovine reproductive tract during the postpartum period. Photographs of uteri collected on (a) postpartum day 1, (b) postpartum day 7, (c) postpartum day 14 and (d) postpartum day 28. Note the changes in shape and conformation of placentomes, as well as the presence of dark fluid (lochia) in the uterine lumen on postpartum days 1 and 7; also note the presence of plaques in the uterine lumen on postpartum day 14.

placental cotyledonary tissue and blood clots (Fig. 2). Numerous blood vessels were observed in the remaining placental cotyledonary tissue on postpartum days 1 and 7. By postpartum day 14, placental cotyledonary tissue was absent from the caruncles. Before postpartum day 28, luminal epithelium was not observed on the residual placentomes or caruncles. On postpartum day 28, the caruncles were everted and contained luminal epithelium covering most, but not all, of the luminal surface.

Cell proliferation and apoptosis

Immunoreactive PCNA protein was used as a marker for cell proliferation (Fig. 3). PCNA is a highly conserved accessary protein of DNA polymerase δ, synthesized during the late G1 and S phases of the cell cycle, essential for DNA synthesis, and correlated with cellular proliferation (Waseem and Lane, 1990). On postpartum days 1 and 7, PCNA protein was most abundant in luminal epithelium and glandular epithelium. In uteri of
postpartum day 14 ewes, PCNA protein was very low or undetectable in all types of cell. However by postpartum day 28, PCNA protein was present in luminal epithelium in a variegated pattern and at low abundance in glandular epithelium. Regardless of postpartum day, little to no PCNA protein was observed in the myometrium or the residual placental tissue.

Staining of \textit{in situ} apoptosis was by DNA end-labelling (Fig. 4). This method recognizes DNA degradation in cells undergoing programmed cell death or apoptosis.
On postpartum day 1, the large, vacuolar, nucleated cells within or between the endometrial glandular epithelia were labelled, but not the luminal epithelium, stroma or myometrium. As expected, the residual conceptus tissue that remained in the uterine lumen after parturition was also labelled.

Analyses by immunofluorescence indicated the presence of CD8⁺ T cells and BAQ44A-defined molecule...
Fig. 4. In situ detection of apoptosis in the ovine uterus on (a,b) postpartum day 1, (c,d) postpartum day 7, (e,f) postpartum day 14 and (g,h) postpartum day 28. The TACS 2TdT DAB Trevigen detection kit was used for identification of apoptotic cells. The photomicrographs in the left column are of the luminal epithelium (LE) and the right column the glandular epithelium (GE). (i) A positive DNase digested control at postpartum day 28. Scale bar represents 100 μm.
Fig. 5. Immunofluorescence detection of immune cells in the postpartum day 1 ovine uterus. (a,b) CD8 cell surface epitope expressed on T cytotoxic cells; (c,d) CD45R cell surface receptor expressed on B cells; (e,f) BAQ44a-defined molecule expressed on B cells and naive T cells; (f,g) immunoreactivity was not observed when irrelevant mouse IgG (mIgG) was substituted for primary antibodies. LE: lumenal epithelium; GE: glandular epithelium. Width of field is 200 μm.

and CD45R+ B cells located within the endometrial luminal and glandular epithelium on postpartum day 1 (Fig. 5). These cells were present in all uteri on all postpartum days, but were most abundant on postpartum days 1 and 7. These cells did not react immunologically with monoclonal antibodies specific for epitopes on T helper cells, monocytes, macrophages, dendritic cells, granulocytes or WC1-positive αβ T cells (data not shown).

The location, number and morphology of these cells indicate that one or both of these immune cell populations represent the apoptotic cells detected by DNA end-labelling.

Steroid hormone receptors in the postpartum uterus

On postpartum day 1, ERα protein was detected in nuclei of epithelial, stromal and myometrial cells (Fig. 6).
The stromal cells of the stratum compactum expressed moderate to abundant amounts of ERα protein. On postpartum day 7 and thereafter, an increase in the overall abundance of ERα protein was detected in the luminal epithelium, stroma and myometrium. In particular, an increase in ERα protein was observed in the endometrial glandular epithelium on postpartum day 7.

Immunoreactive PR protein was not detected in the nuclei of any epithelia on postpartum day 1 (Fig. 6). However, moderate to abundant amounts of PR protein were detected in cells of the stroma and myometrium. By postpartum day 7, abundant PR protein was detected in the superficial glandular epithelium of the stratum compactum as well as glandular epithelium present in the upper stratum spongiosum. Between postpartum days 7 and 28, PR protein was either very low or absent in luminal epithelium, but moderate or abundant in the stroma and myometrium. During this period, PR protein was observed in all superficial and middle endometrial glandular epithelium, but absent in the deeper glandular epithelium.
Expression of PRLR, OTR and UTMP

Expression of PRLR mRNA was detected only in the endometrial glandular epithelium and did not appear to be affected by postpartum day (Fig. 7). In comparison with the sense control, no specific hybridization signal was detected in the residual placenta, stroma, myometrium or luminal epithelium. In the endometrium, OTR mRNA was detected in the luminal epithelium and glandular epithelium of all ewes regardless of postpartum day. Expression of the OTR mRNA was most abundant in the endometrial luminal epithelium with lower expression in the glandular epithelium and myometrium. On postpartum day 1, UTMP mRNA was detected only in the endometrial glandular epithelium of the stratum spongiosum, but not in the superficial glandular epithelium in the stratum compactum. In contrast to postpartum day 1, UTMP mRNA was not detected in the endometrial glands or any other type of cell between postpartum days 7 and 28.

Discussion

During the postpartum period, involution of the uterus occurs in preparation for the ewe to resume oestrous cycles. Indeed, ewes exhibit decreased conception
rates for up to 40 days postpartum (Kiracofo, 1980). As observed in previous studies (van Wyk et al., 1972a,b; O’Shea and Wright, 1984), three overlapping events occurred in the involuting ovine uterus: (1) an overall reduction in uterine size; (2) loss of conceptus tissue; and (3) tissue repair. Marked reductions in uterine wet mass (7.8-fold) and horn length (2.4-fold) were accompanied by a thinning of both the endometrium and myometrium. A noticeable decrease in the extracellular space of the endometrial stroma and an increase in ECM were detected histologically. Although changes in the ECM are involved in placentation (Ott et al., 1997), little information is available on the composition and changes in the ECM of the uterus during pregnancy or any other period of morphogenesis. Histological analyses indicated that tissue remodelling occurred in both the caruncular and intercaruncular areas of the uterine wall. This tissue remodelling did not appear to involve programmed cell death, because DNA fragmentation was observed only in the large, vacuolated cells surrounding the endometrial glands on postpartum days 1 and 7. O’Shea and Wright (1984) suggested that these cells were dying glandular epithelium cells. However, these large cells are similar in morphology to intraepithelial lymphocytes. Immunofluorescence analyses found that these cells exhibit antigens consistent with a mixed population of lymphocytes consisting of T and B cells. Large numbers of intraepithelial immune cells in the endometrial glands have been reported during uterine development and gestation (Wimsatt, 1950; Wiley et al., 1987). Specifically, CD45R and CD8 positive immune cells are expressed in the epithelium of ewes during the oestrous cycle and early pregnancy (Segerson et al., 1991; Lee et al., 1988). Furthermore, these intraepithelial endometrial immune cells are regulated by circulating concentrations of progesterone (Gottshall and Hansen, 1992). Cell proliferation, as detected by immunoreactive PCNA distribution, was detected in the endometrial epithelia, but not in the stroma or myometrium. The simultaneous occurrence of cellular apoptosis and proliferation accompanied by remodelling of the ECM is similar to that described for mammary gland involution (Takamoto et al., 1998; Wiesen and Werb, 2000; Capuko et al., 2002). Collectively, available results indicate that the marked reductions in uterine size and horn length are due to remodelling of the ECM, loss of tissue hydration, and reduction in uterine blood flow and vascularity rather than to apoptosis.

In the caruncular areas of the uterus, loss of conceptus tissue and maternal tissue repair in the caruncle were observed between postpartum days 1 and 28. A major remodelling event was removal of the remaining placent al cotyledonary tissue from the maternal caruncles between postpartum days 1 and 14. On postpartum day 1, the caruncles appeared distended, with a concave dark brown centre, which contained the residual portions of the placental cotyledons that form plaques. During this period, the uterine lumen contained a large amount of lochia. This thick, brownish dark fluid was generated at parturition from the leakage of blood from the extensive vascular bed of the placenta that provided haematotrophic nutrition to the fetus (van Wyk et al., 1972a). Between postpartum days 7 and 14, the residual placental cotyledons formed plaques that were released into the uterine lumen. However, these plaques were absent on postpartum day 28, presumably due to autolysis and resorption by the uterus. In addition to changes in tissue composition and shape, a marked reduction in vascularity was also observed in both caruncular and intercaruncular areas of the uterine wall during involution. By postpartum day 28, the caruncular areas of the endometrium had remodelled from a concave to a convex shape. Between postpartum days 14 and 28, the eversion of the caruncles was accompanied by re-epithelialization. Although this process was not complete on postpartum day 28, it is probably a key indicator of completion of uterine involution and process in return to cyclicity. The endometrial luminal epithelium and superficial glandular epithelium are critical for cyclicity, because they produce the luteolysin, prostaglandin F2α (PGF2α). Luteolytic pulses of PGF2α are produced in response to the binding of oxytocin, produced by the posterior pituitary gland and corpus luteum, to OTR on the endometrial epithelia (see Bazer et al., 1998). Absence of either the luminal epithelium or superficial glandular epithelium renders the uterus incapable of producing luteolytic PGF2α pulses and causes acyclicity (Gray et al., 2000a). Therefore, one aspect of involution is an increase in number of OTR and the ability to produce PGF2α as a consequence of re-epithelialization, or regrowth of the epithelium, of the endometrial caruncles. In addition to the remodelling of the caruncular areas of the uterus and overall reduction in uterine size and horn length, the intercaruncular areas of the uterine wall and, in particular the endometrial glands, also exhibited retrograde changes. During pregnancy, hyperplasia and hypertrophy of the endometrial glands occurs to provide increasing amounts of histotrophic nutrition to the rapidly growing conceptus (Wimsatt, 1950; Stewart et al., 2000). Indeed, the overall secretory capacity of the uterus parallels growth and development of the fetus (Moffat et al., 1987; Stewart et al., 2000). A hormonal servomechanism involving oestrogen, progesterone, IFN-τ, PL and placental GH was proposed to regulate endometrial gland morphogenesis and differentiated function (Spencer et al., 1999; Stewart et al., 2000; Noel et al., 2003). A key feature of this servomechanism is negative autoregulation of PR gene expression in the endometrial glandular epithelium by progesterone. During early pregnancy, PR gene expression becomes undetectable in the glandular epithelium after day 13 (Spencer and Bazer,
1995) before the induction of UTMP expression between days 15 and 17 (Stewart et al., 2000). In ovariectomized ewes, treatment with progesterone downregulates PR expression, which is followed by the appearance of OPN and then UTMP expression in the endometrial glands (Mofiat et al., 1987; Ing and Roberts, 1989; Spencer et al., 1999); however, addition of oestradiol to progesterone treatment prevents induction of UTMP expression by upregulating PR, an oestrogen-responsive gene in glandular epithelium (Spencer et al., 1999).

Results from the present study lend strong support to the idea that progesterone-induced downregulation of the PR gene in the endometrial glandular epithelium is required for glandular epithelium differentiation and production of secretory proteins such as the UTMPs. Serum concentration of oestradiol were high at parturition and then peaked again on postpartum day 6. These temporal changes in circulating oestradiol and a lack of progesterone can be correlated with the increase in ERα protein and OTR mRNA and induction of PR protein between postpartum days 1 and 7, which was associated with a concomitant loss of UTMP expression in the endometrial glandular epithelium. Available evidence indicates that PL acts via the PRLR to increase UTMP gene expression (Spencer et al., 1999; Herman et al., 2000). Although the cellular and molecular mechanism(s) is unknown, PR downregulation is required for PL stimulation of UTMP expression (Spencer et al., 1999). Expression of the UTMPs is a marker of differentiated glandular epithelium function. Therefore, the absence of UTMP expression and the reduction in endometrial gland width during the postpartum period indicate that the hormonal servomechanism regulating uterine gland morphogenesis during pregnancy is terminated during involution. Termination of this servomechanism appears to involve increases in ERα and PR expression rather than alterations in PRLR expression or cell death. Increased knowledge of the hormonal, cellular and molecular mechanisms regulating uterine involution is necessary to develop therapies to treat postpartum infertility and aneustria in order to maximize reproductive efficiency.

The authors thank T. Welsh and T. Bryan at Texas A&M University for assistance with radioimmunoassay; R. C. Burghardt at Texas A&M University for assistance with immunofluorescence analyses; W. Davis at Washington State University for immune cell surface antibodies and helpful discussion; and F. W. Bazer at Texas A&M University for helpful discussion.
