Inositol transport in preimplantation rabbit embryos: effects of embryo stage, sodium, osmolality and metabolic inhibitors

S. M. Warner, F. V. Conlon and M. T. Kane*

Department of Physiology, National University of Ireland, Galway, University Road, Galway, Ireland

The preimplantation period in the rabbit consists of a 3 day cleavage stage during which the number of cells increases with little change in embryo size, followed by a 3–4 day blastocyst stage during which the inner cell mass, the blastocoel and the trophoblastic layer are formed and the embryo grows rapidly in size and protein content. This study used [3H]inositol to investigate the transport of inositol, an essential component of the phosphatidylinositol signal transduction system, over the 6 days of preimplantation development by rabbit embryos.

In the presence of 15 μmol inositol l⁻¹ in the incubation medium, there was a small linear increase in inositol uptake from 0.07 pmol per embryo per h at the one-cell stage (day 1) to 0.135 pmol at the late morula (day 3) stage. Inositol uptake increased to 0.58 pmol per embryo per h for early blastocysts (day 4) and 23.7 pmol for late blastocysts (day 6). There was a significant linear relationship between inositol uptake and blastocyst diameter and surface area. Efflux of inositol from early morulae was minimal (about 1.25% of embryo content per h), whereas efflux from mid-blastocysts (day 5) was much greater (about 15.6% of embryo content per h). Efflux of inositol from both early morulae and mid-blastocysts was increased by decreasing the osmolality of the incubation medium. Varying the osmolality had no effect on inositol uptake up to 2 h. Inositol uptake was dependent on sodium in cleavage-stage embryos but independent of sodium in blastocyst stages. In early morulae, inositol uptake was inhibited by glucose and the sodium-dependent hexose transport inhibitor, phloridzin, but not by the facilitated transport inhibitor, phloretin. Inositol uptake in early morulae was saturable; estimates of 0.227 and 0.288 pmol per morula per h for Vₘₐₓ and 0.045 and 0.038 μmol l⁻¹ for Kₘ were obtained for sodium-dependent transport in two separate experiments. All of these results are consistent with the hypothesis that transport in cleavage stages occurs via a sodium myo-inositol transporter (SMIT) protein. Uptake into blastocysts was non-saturable. Uptake into blastocysts appeared to take place by a transcellular rather than a paracellular route.

Introduction

There is wide research interest in the various roles of inositol, inositol phosphates and phosphoinositides in cell function. Inositol itself acts as a controller of cell volume and osmolality in certain types of cell (for reviews, see Kleinzeller and Ziyadeh, 1990; Burg, 1995).

Glycosylphosphoinositides are used by cells to anchor some proteins to the cell membrane (for review, see Ferguson, 1999) and, related to this, there is evidence that an inositol phosphate glycan may act as an intracellular messenger for insulin (for review, see Jones and Varela-Nieto, 1998). There is also evidence that a polyphosphoinositide, phosphatidylinositol 3,4,5-trisphosphate, may function as a second messenger for certain growth factors (for reviews, see Varticovski et al., 1994; Leevers et al., 1999). However, most research interest is centered on the phosphatidylinositol (PtdIns) cycle and its role as a signal transduction system for various neurotransmitters, hormones and growth factors (for reviews, see Berridge, 1992; Shears, 1998). Stimulation of membrane-bound cell receptors by a hormone or other agonist activates phospholipase C to break down PtdIns(4,5)P₂ to two second messengers, inositol 1,4,5-trisphosphate (Ins(1,4,5)P₃) and diacylglycerol. Ins(1,4,5)P₃ increases intracellular Ca²⁺ concentrations and diacylglycerol activates protein kinase C, which alters cell function by phosphorylating a range of cell proteins.

The rabbit embryo is a particularly interesting system in which to study the effects of growth factors and their signal transduction systems in early embryos because, unlike other laboratory species, it exhibits a marked increase in growth and protein content during the preimplantation period (see Fig. 1). The protein content and number of cells increase from about 0.16 μg protein at the one-cell stage immediately after fertilization (Morgan and Kane, 1993) to about 7 μg protein and about 80 000 cells in the day 6 blastocyst just before implantation (Daniel, 1964; Morgan and Kane, 1993). In contrast, the mouse blastocyst at implantation has...
<100 cells and 20–40 ng of protein (Schiffrin and Spielmann, 1976). Related to this difference in pre-implantation growth patterns is the difficulty in culturing blastocyst-stage rabbit embryos *in vitro*. Unlike mouse embryos, the formation and expansion of rabbit blastocysts requires the presence of amino acids and water-soluble vitamins, and growth *in vitro* is markedly less than growth *in utero* (for review, see Kane, 1987).

One of the vitamins essential for rabbit blastocyst expansion and growth is *myo*-inositol (Kane, 1988; Fahy and Kane, 1992) and inositol also stimulates zona pellucida shedding or ‘hatching’ by hamster blastocysts (Kane and Bavister, 1988). It has been demonstrated that [*H*]inositol is incorporated into the phosphoinositides and inositol phosphates of the PtdIns cycle by rabbit and cattle blastocysts (Fahy and Kane, 1993; Hynes et al., 2000), and into PtdIns and PtdIns4P by mouse blastocysts (Kane et al., 1992; Higgins and Kane, 2003).

The present study set out to investigate the transport of *myo*-inositol by rabbit embryos over the 6 days of preimplantation development. The mouse and cow are the only other species in which inositol uptake has been studied in preimplantation embryos; in mice there is a large increase in inositol uptake at the blastocyst stage that is not related to embryo protein content (Kane et al., 1992), whereas in cattle embryos there is little increase in uptake at blastocyst formation (Hynes et al., 2000).

**Materials and Methods**

**Collection and incubation of embryos**

All embryos were collected from does primed with FSH, ovulated with hCG and artificially inseminated (Kane, 1987). Embryos were collected via a mid-ventral laparotomy under neuroleptoanalgesia (Green, 1975) using Hypnorm (active ingredient, fluanisone) as the anesthetic (Kane, 1987). Embryos were washed three times by transfer through collection medium and then incubated at 38.5°C in rabbit embryo culture medium under 5% CO₂ in air. The composition of the rabbit embryo culture medium (sodium plus medium) was 0.5% (w/v) BSA and 108 mmol NaCl l⁻¹, 4.78 mmol KCl l⁻¹, 1.71 mmol CaCl₂·2H₂O l⁻¹, 1.19 mmol KH₂PO₄ l⁻¹, 1.19 mmol MgSO₄·7H₂O l⁻¹, 25 mmol NaHCO₃ l⁻¹ and 0.5 mmol sodium pyruvate l⁻¹. The concentrations of amino acids, vitamins and trace elements were the same as in Ham’s F10 medium (Ham, 1963; Kane and Foote, 1970) with two exceptions: the serine concentration was 3 mmol l⁻¹ (Kane, 1989) and the *myo*-inositol concentration varied with the experiment. This medium was used in all experiments unless otherwise stated.

A sodium minus medium was made by replacing NaCl in the standard medium with choline chloride and replacing NaHCO₃ with choline bicarbonate on an equimolar basis to study the effect of sodium. However, this medium contained minor amounts of sodium both from sodium pyruvate (0.5 mmol l⁻¹) and from the sodium salts of some amino acids. Media of various osmolalities were made up by varying the total amount of water in the media; osmolalities were checked with a freezing-point depression osmometer. For the experiment to study the effect of temperature, a Hepes-buffered medium with a similar composition to the sodium plus medium was prepared with the exception that NaHCO₃ was replaced by 10 mmol Hepes l⁻¹ and the osmolality was adjusted by changes in NaCl concentration.

Day 1–4 embryos were usually incubated in 100 µl drops of medium under liquid paraffin in Nunc four-well dishes. Day 5–6 embryos were incubated in 1 ml medium in Nunc four-well dishes. The duration of incubation, except where otherwise specified, was 2 h. In certain experiments, late blastocysts were ruptured using a 21 G hypodermic needle and the resultant clump of cells from each blastocyst, which remained together as a discrete unit, was incubated to study inositol uptake.

**Measurement of [*H*]inositol uptake by embryos**

The [*H*]inositol used was *myo*-[2-*H*]inositol (NEN, DuPont de Nemours, Bad Homborg; specific activity varying from 20.0 to 24.4 Ci mmol l⁻¹). On the basis of the data from the first experiment, the concentration of [*H*]inositol used in later experiments was adjusted to take account of both the number and stage of embryos used; however, where treatment comparisons were made, concentrations of [*H*]inositol were the same across treatments. As described in the protocol of the various experiments, the embryos were washed through three or four drops (about 4 ml per drop) of Hepes-buffered collection medium after incubation. The embryos were then placed in a scintillation vial in 0.5 ml 10% (w/v) trichloroacetic acid, after which 10 ml scintillation cocktail (Ready Value, Beckman Coulter, High Wycombe) was added; a small volume of the final wash medium equivalent to the volume in which washed embryos were transferred to the scintillation vial was treated in a similar way, as a control. The samples
were counted in a liquid scintillation counter. The d.p.m. values and specific activity of the [3H]inositol in the culture medium were used to calculate inositol uptake expressed as pmol per embryo per h. Uptake was also expressed as pmol per cm² per h for blastocysts.

**Experiment 1: effect of embryo stage on inositol uptake**

Embryos of all six stages from days 1–6 were incubated for 2 h in either 100 µl (days 1–4) or 1 ml (days 5–6) drops of medium containing 10 µCi [3H]inositol ml⁻¹. Concentration of unlabelled inositol was 15 µmol l⁻¹, the concentration shown to be optimal for rabbit blastocyst growth in vitro (Kane, 1989; Fahy and Kane, 1992).

**Experiment 2: effect of duration of incubation and temperature on inositol uptake**

The effects of duration of incubation on inositol uptake were examined by incubating day 2 early morulae and day 5 mid-blastocysts in drops of medium (morulae, 100 µl; blastocysts, 1 ml) containing 25 µCi [3H]inositol ml⁻¹ for 10, 20, 40, 60, 120 or 240 min. Concentration of unlabelled inositol was 15 µmol l⁻¹.

The effects of temperature in day 2 early morulae, and day 6 intact blastocysts and clumped blastocyst cells incubated in Heps-buffered medium for 2 h at 8°C and 38°C were examined. Morulae and blastocyst cells were incubated in 100 µl drops with either 100 (morulae) or 50 (blastocyst cells) µCi [3H]inositol ml⁻¹. Intact blastocysts were incubated in 1 ml drops with 5 µCi [3H]inositol ml⁻¹. Concentration of unlabelled inositol was 3 µmol l⁻¹.

**Experiment 3: effect of embryo stage on efflux of [3H]inositol**

Efflux of [3H]inositol from day 2 early morulae and day 5 mid-blastocysts was examined. Embryos were preloaded with [3H]inositol by incubation for 6 h in drops (morulae, 100 µl; blastocysts, 1 ml) of medium without unlabelled inositol but in the presence of either 100 (morulae) or 10 (blastocysts) µCi [3H]inositol ml⁻¹. At the end of the loading period, embryos were removed from the drops, washed three times by transfer to collection medium and then re-incubated in drops of unlabelled medium (morulae, 0.5 ml; blastocysts, 1 ml) for 2 h and the leakage of inositol from the embryos was quantified.

**Experiment 4: sodium dependency of inositol uptake**

Embryos of all six stages from days 1–6 were incubated for 2 h in either 100 µl (days 1–4) or 1 ml (days 5–6) drops of medium, both in sodium plus and sodium minus medium, in the presence of 10 µCi [3H]inositol ml⁻¹. The concentration of unlabelled inositol was 15 µmol l⁻¹.

**Experiment 5: effects of glucose and metabolic inhibitors on inositol transport by morulae**

Day 2 early morulae were incubated for 2 h in 100 µl drops in media containing glucose (5 mmol l⁻¹), phloridzin (0.05 mmol l⁻¹) or phloretin (0.1 mmol l⁻¹) in the presence of 50 µCi [3H]inositol ml⁻¹. Concentration of unlabelled inositol was 3 µmol l⁻¹. The concentration of phloridzin chosen was that known to cause inhibition of sodium-dependent glucose transport (Schultz and Zalusky, 1964); the concentration of phloretin used was that shown by Robinson et al. (1990) to cause 95% inhibition of sodium-independent glucose transport by rabbit blastocysts. A control treatment with ethanol was used for these treatments because phloridzin and phloretin were dissolved in ethanol.

**Experiment 6: effects of osmolality on uptake and efflux of inositol by embryos**

For uptake studies, embryos were incubated in media of various osmolalities (mOsmol (kg water)⁻¹; low, 100–180; normal, 255–262; high, 340–355). Day 2 early morulae were incubated for 40 min in 100 µl drops with 50 µCi [3H]inositol ml⁻¹ and 3 µmol l⁻¹ unlabelled inositol. Day 5 mid-blastocysts were incubated for 40 min and 120 min in 1 ml drops with 10 µCi [3H]inositol ml⁻¹. The concentration of unlabelled inositol was 3 µmol l⁻¹.

After loading with [3H]inositol, embryos were incubated in media of various osmolalities as described above and efflux was measured. Day 2 early morulae were loaded with [3H]inositol by placing them for 6 h in 100 µl drops in normal medium without unlabelled inositol but with 50 µCi [3H]inositol ml⁻¹. At the end of the loading period the embryos were washed three times with unlabelled collection medium and then placed in 0.5 ml drops (5–10 morulae per drop) of unlabelled medium of the different osmolalities for measurement of efflux. A 25 µl sample of medium was taken at time 0 and the embryos were then incubated for 40 min. At the end of incubation, the embryos and incubation medium were removed separately for counting. Day 5 mid-blastocysts were loaded with [3H]inositol by placing them for 6 h in 1 ml drops in normal medium without unlabelled inositol but with 10 µCi [3H]inositol ml⁻¹. At the end of the loading period, the embryos were washed three times with unlabelled collection medium and then placed in 1 ml drops (one blastocyst per drop) in media of the different osmolalities for measurement of efflux. Samples (25 µl) of the incubation medium were taken for counting at 0, 20, 40, 60, 80, 100 or 120 min after the start of incubation. At the end of 120 min incubation, embryos were removed, washed and counted.

**Experiment 7: kinetics of inositol uptake**

The kinetics of inositol uptake by early morulae were examined in two experiments by incubating...
Fig. 1. Rabbit embryos during the 6 days of preimplantation development. (a) The relative sizes of rabbit embryos; sizes refer to embryos without the embryonic coverings (zona pellucida and mucin coat). Filled circles indicate the cleavage or pre-blastocyst stages; open circles indicate the blastocyst stages, all of which possess a blastocoel surrounded by a unicellular layer, trophoblast or trophectoderm. The relatively small inner cell mass from which all the tissues are derived is contained within the blastocyst. Data on the relative sizes of embryos are taken from Alliston and Pardee (1973). (b) A day 2 early morula (ZP, zona pellucida; MC, mucin coat) and (c) a day 4 early blastocyst (T, trophoblast or trophectoderm; ICM, inner cell mass). Scale bars represent (a) 1 mm, (b) 50 μm and (c) 100 μm.

Embryos for 2 h in small groups in 50 μl drops (5–13 embryos per drop), in sodium plus and sodium minus media, in the presence of 100 μCi [3H]inositol ml⁻¹ and concentrations of unlabelled inositol varying from 10 μmol l⁻¹ to 5 mmol l⁻¹, and measuring radioactivity in the embryos at the end of incubation. Sodium-dependent transport for each concentration of inositol was calculated by subtracting transport in the absence
of sodium from transport in the presence of sodium and from these data K_m and V_max values for sodium-dependent transport were determined using Eadie-Hofstee plots.

Day 5 mid-blastocysts were incubated for 2 h in sodium plus medium in 250 μl drops in the presence of 25 μCi [³H]inositol ml⁻¹ and various concentrations of unlabelled inositol (10 μmol l⁻¹−5 mmol l⁻¹).

Experiment 8: effect of inositol concentration in the incubation medium on distribution of inositol uptake between blastocyst cells and blastocyst fluid

Day 6 late blastocysts were incubated for 2 h in 1 ml drops in the presence of 10 μCi [³H]inositol ml⁻¹ and various concentrations of unlabelled inositol (10 μmol l⁻¹−50 mmol l⁻¹). At the end of incubation the embryos were removed, washed three times and placed in a culture dish. Surplus medium was aspirated with a fine needle; the blastocysts were burst and the blastocyst fluid and clump of blastocyst cells were collected separately and inositol uptake into each was quantified.

Experiment 9: effect of duration of incubation and concentration of unlabelled inositol on the uptake of [³H]inositol by isolated blastocyst cells

Day 6 late blastocysts were burst and the clumped cells from each blastocyst incubated in 1 ml drops of medium in the presence of 5 μCi [³H]inositol ml⁻¹ and either 10 μmol l⁻¹ or 5 mmol l⁻¹ unlabelled inositol. At the end of 4, 20 or 120 min incubation, blastocysts were removed and inositol uptake was quantified.

Experiment 10: evidence for a cellular versus paracellular entry of inositol into the blastocyst cavity

In an effort to determine whether inositol enters the blastocyst first via the cells and then leaks into the blastocyst cavity (transcellular route) or enters via the trophodermal junctions and is then taken up from the blastocyst fluid by the cells, the partitioning of [³H]inositol between blastocyst cells and then leaks into the blastocyst cavity (transcellular route) or enters via the paracellular route of unlabelled inositol uptake from the incubation medium on distribution of inositol uptake into blastocyst cells and blastocyst fluid.

The uptake of [³H]inositol by blastocyst cells and fluid was measured and expressed in d.p.m. per μl using the following equation:

\[ V = \frac{4}{3} \pi [r^3 - (r - s)^3] \]

where \( V \) = volume of cells, \( r \) = blastocyst radius and \( s \) = shell or trophoblastic wall thickness (taken as 6 μm).

The uptake of [³H]inositol by blastocyst cells and fluid was measured and expressed in d.p.m. per μl using...
Fig. 3. Relationship between uptake of inositol and blastocyst diameter for day 4, 5 and 6 rabbit blastocysts. There was a significant \((P < 0.001)\) linear relationship between inositol uptake and blastocyst diameter with a correlation coefficient \(r = 0.903\). There was also a significant \((P < 0.001)\) linear relationship between inositol uptake and blastocyst surface area \((r = 0.851, \text{data not shown})\). Inset shows the relationship between uptake of inositol and blastocyst diameter for day 4 blastocysts only \((r = 0.931)\).

Fig. 4. Effect of duration of incubation on accumulation of inositol by rabbit embryos. (a) Morulae on a per embryo basis and (b) mid-blastocysts on a per \(\text{cm}^2\) surface area basis. Concentration of unlabelled inositol was 15 \(\mu\text{mol l}^{-1}\). Values are means \(\pm\) SEM and individual graph points are based on three or four morulae (a total of 50 morulae from two rabbits) and one blastocyst (a total of 35 blastocysts from three rabbits). There was a significant linear relationship \((P < 0.001)\) between duration of incubation and inositol uptake in both morulae and blastocysts; in blastocysts there was also a significant \((P < 0.01)\) quadratic component.

**Results**

**Experiment 1: effect of embryo stage on inositol uptake**

The uptake of inositol by rabbit embryos of all six stages from day 1 to day 6 was stage specific (Fig. 2). For the cleavage or pre-blastocyst stages there was a modest but significant \((P < 0.05)\) linear increase in inositol uptake from 0.07 pmol per embryo per h at the one-cell stage (day 1) to 0.135 pmol per embryo per h at the late morula (day 3) stage. However, at the blastocyst stages, as the embryos grew and expanded, there was a huge increase in inositol uptake to 0.58 pmol per embryo.

Intact blastocysts

Fig. 5. Effects of temperature, 8°C (□) and 38°C (■), on uptake of inositol by (a) day 2 rabbit morulae and (b) day 6 rabbit blastocysts (intact blastocysts and clumped blastocyst cells). Concentration of unlabelled inositol was 15 μmol l⁻¹. Values are means ± SEM and details of embryos are as follows: morulae, 12 replicates of 4–7 morulae per treatment (a total of 136 morulae from four rabbits); blastocyst cells, 13–14 replicates of one blastocyst per treatment (27 blastocysts from four rabbits); intact blastocysts, 14–15 replicates of one blastocyst per treatment (29 blastocysts from four rabbits). ***P < 0.001.

Experiment 2: effect of duration of incubation and temperature on inositol uptake

Uptake of inositol by early morulae was linear (P < 0.001) for the whole 240 min examined (Fig. 4); in contrast, uptake by mid-blastocysts levelled off after 120 min as evidenced by a significant quadratic component (P < 0.01).

Experiment 3: effect of embryo stage on efflux of [³H]inositol

Efflux of [³H]inositol from early morulae was minimal, and was about 1.25% of the original embryo content per h (inositol leaked after 2 h, 189 ± 26 d.p.m; inositol retained 7444 ± 162 d.p.m.). In contrast, efflux from mid-blastocysts was much greater, about 15.6% of embryo content per h (inositol leaked after 2 h, 8123 ± 848 d.p.m; inositol retained 26103 ± 2888 d.p.m.), indicating that in 6 h (equivalent to the time taken to load the blastocysts with [³H]inositol in this experiment), assuming a constant efflux rate, almost all the inositol would be expected to leak out again.

Experiment 4: sodium dependency of inositol uptake

The effect of sodium on the uptake of inositol by cleavage-stage rabbit embryos (days 1–3) and blastocyst stages (days 4–6) is shown (Fig. 6). There was a marked difference between cleavage-stage and blastocyst-stage embryos in the effect of sodium on inositol uptake. Removal of sodium from the medium almost completely abolished inositol uptake by cleavage-stage embryos.

Bar graphs show uptake in sodium plus (■) and sodium minus (□) medium. (a) Uptake of inositol per embryo in cleavage-stage embryos; (b) uptake of inositol per embryo in blastocyst stages; and (c) uptake of inositol per cm² of surface area in blastocyst stages. Concentration of unlabelled inositol was 15 μmol l⁻¹. Values are means ± SEM. Details of embryos used are as follows: one-cell embryos, six replicates of 3–5 embryos per replicate for a total of 27–28 embryos per treatment (embryos from two rabbits); early morulae, four replicates of 3–7 embryos per replicate for a total of 20–21 embryos per treatment (embryos from two rabbits); late morulae, three replicates of four embryos per replicate for a total of 12 embryos per treatment (embryos from one rabbit); early blastocysts, 9–10 replicates of 1–3 embryos per replicate for a total of 15–18 embryos per treatment (embryos from three rabbits); mid-blastocysts, 17–18 replicates of one embryo per replicate for a total of 17–18 embryos per treatment (embryos from two rabbits); late blastocysts, 13–14 replicates of one embryo per replicate for a total of 13–14 embryos per treatment (embryos from three rabbits). There was a significant effect (P < 0.01) of sodium on uptake of inositol by all cleavage stages but no significant effect on uptake in blastocyst stages.
Inositol transport in rabbit embryos

Fig. 7. Effect of (a) glucose (5 mmol l\(^{-1}\)) and (b) the metabolic inhibitors phloridzin (0.05 mmol l\(^{-1}\)) and phloretin (0.1 mmol l\(^{-1}\)) on uptake of \(\text{[^3H]inositol}\) by rabbit early morulae. Results are presented as d.p.m. per morula per h because in four or five of the replicates for each treatment the unlabelled inositol (3 \(\mu\)mol l\(^{-1}\)) was omitted from the medium. Values are means ± SEM based on 12–13 replicates of 1–4 morulae per replicate per drop (total of 182 embryos from 18 rabbits). *P < 0.05, **P < 0.01.

Fig. 8. Effect of osmolality of the incubation medium on uptake of inositol by rabbit morulae and blastocysts. (a) Day 2 early morulae after 40 min incubation with 50 \(\mu\)Ci \(\text{[^3H]inositol}\) ml\(^{-1}\) and 3 \(\mu\)mol l\(^{-1}\) unlabelled inositol. (b) Day 5 mid-blastocysts with 10 \(\mu\)Ci \(\text{[^3H]inositol}\) ml\(^{-1}\) and 3 \(\mu\)mol unlabelled inositol l\(^{-1}\). Osmolality concentrations (mOsmol (kg water)\(^{-1}\)) were as follows: low [], 180–188; normal [], 255–262; high [], 340–355. Values are means ± SEM based on three replicates of 3–8 morulae per treatment (a total of 46 morulae from three rabbits), and 5–6 replicates of one blastocyst per treatment at each time point (33 blastocysts from four rabbits). There was no significant effect of osmolality on inositol uptake by morulae or blastocysts.
Fig. 9. Effect of osmolality of the incubation medium on efflux of [3H]inositol from rabbit morulae and blastocysts. (a) Day 2 early morulae after 40 min of incubation. (b) Day 5 mid-blastocysts. Osmolality concentrations (mOsmol (kg water)$^{-1}$) were as follows: low (◇), 180–188; normal (□), 255–262; high (■), 340–355. Values at each time point are means ± SEM based on 23–24 replicates of one blastocyst per treatment (a total of 69 blastocysts from six rabbits). *P < 0.05, **P < 0.01, ***P < 0.001.

Fig. 10. Effects of inositol concentration in the incubation medium on uptake of inositol by day 2 rabbit early morulae. Plotted points are based on total inositol concentration which includes both labelled and unlabelled inositol. Sodium plus medium, ◇; sodium minus medium, □. Inset: uptake in the concentration range 0–0.6 mmol inositol l$^{-1}$. Values are means ± SEM based on the combined data from two replicate experiments. Details of embryos are provided in Fig. 11.

In contrast, uptake of inositol by whole blastocysts was not saturable from 0 to 5 mmol l$^{-1}$ (Fig. 12). Data from other experiments (not shown) indicate that even at a concentration of 50 mmol l$^{-1}$ there was no evidence for saturation of the transport process in blastocysts.

Experiment 8: effect of inositol concentration in the incubation medium on distribution of inositol uptake between blastocyst cells and blastocyst fluid

Incubation of blastocysts in various concentrations of unlabelled inositol for 2 h followed by separation of the cells and blastocyst fluid showed that at a low unlabelled inositol concentration in the medium (10 μmol l$^{-1}$), the total amount of inositol taken up into the cells was slightly greater than that in the fluid (Fig. 13); however, with increasing unlabelled inositol concentration, uptake into the cells tended to level off but uptake into the fluid increased in a linear fashion. This finding indicates that either the rate of uptake of inositol into the blastocyst cells or retention by these cells is saturable. The next experiment examined which of these alternatives is valid.
Fig. 11. Kinetics of sodium-dependent inositol transport in rabbit morulae. (a) and (b) are two replicate experiments. Eadie-Hofstee plots for measurement of $K_m$ and $V_{max}$ values for sodium-dependent transport in day 2 early morulae. $V$ = inositol uptake; $S$ = inositol concentration. Numbers of morulae for each data point are shown in insets.

Fig. 12. Effects of inositol concentration in sodium plus incubation medium on uptake of inositol by day 5 rabbit mid-blastocysts.Inset shows uptake per cm$^2$. Results are means ± SEM based on 7–11 replicates of one blastocyst for each inositol concentration (a total of 60 blastocysts from six rabbits).

Experiment 9: effect of duration of incubation and concentration of unlabelled inositol on the uptake of [$^3$H]inositol by isolated blastocyst cells

When clumped cells from ruptured late blastocysts were incubated for 120 min, a high concentration of unlabelled inositol (5 mmol l$^{-1}$) markedly reduced net uptake of [$^3$H]inositol compared with a lower concentration (10 $\mu$mol l$^{-1}$; Fig. 14). However, when incubation time was reduced to 4 min, the inhibitory effect of the high concentration of unlabelled inositol

Values are means ± SEM. Method A: the volume of cells was calculated based on the length of the cell plug in the capillary pipette; and the volume of blastocyst fluid was estimated by subtracting that volume from the volume of the blastocyst. Because the plug of cells was not packed by centrifugation this method tends to give an upper limit to the volume of the blastocyst cells. Method B: blastocyst cell volumes were calculated using the equation described by Jung and Fischer (1988) for rabbit blastocysts:

\[ V = \frac{4}{3} \pi r^3 - (r - s)^3 \]

where \( V \) = volume of cells, \( r \) = blastocyst radius and \( s \) = shell or trophoblastic wall thickness (taken as 6 μm).

Fig. 14. Effect of duration of incubation and concentration of unlabelled inositol on accumulation of [³H]inositol by rabbit blastocyst cells (day 6, late blastocysts). Concentrations of unlabelled inositol: 10 μmol l⁻¹ (□); 5 mmol l⁻¹ (■). Values are means ± SEM based on 6–11 blastocysts per inositol concentration at each time point, for a total of 48 embryos from three rabbits. Inset shows effect of duration of incubation on ratio of accumulated [³H]inositol in blastocysts incubated with 10 μmol l⁻¹ and 5 mmol l⁻¹ unlabelled inositol. There was a significant (\( P < 0.001 \)) effect of both duration of incubation and concentration of unlabelled inositol on uptake of [³H]inositol; there was also a significant (\( P < 0.001 \)) interaction between the effect of duration of incubation and concentration of unlabelled inositol on uptake.

was much less marked; extrapolation of the line showing the ratio of inositol uptakes for the two concentrations of unlabelled inositol at different incubation times (Fig. 14, inset) gives a ratio of close to one for an incubation time of 1 min, indicating that high concentrations of unlabelled inositol do not inhibit the initial uptake rate. This result indicates that the uptake process per se in blastocyst cells is not saturable but that there is a saturable binding process for inositol within the cells which affects cellular accumulation and retention of inositol.

Experiment 10: evidence for a cellular versus paracellular entry of inositol into the blastocyst cavity

Partitioning of [³H]inositol taken up by late blastocysts between blastocyst cells and fluid after short-term incubation (2 min) was measured in terms of d.p.m. per unit volume between blastocyst cells and fluid per blastocyst. The mean of the ratios between cells and fluid using the direct measurement method of estimating blastocyst cell volume (method A, Table 1) was 9.64 ± 1.95 and, using the method of Jung and Fischer (1988), was 17.15 ± 3.19 (method B, Table 1). As the concentration is in the region of 9–17-fold higher per unit volume in the blastocyst cells compared with blastocyst fluid after short-term incubation, this indicates that the inositol first enters the blastocyst cells and from there passes into the blastocyst fluid (transcellular route) rather than the other way around. The difference between the two estimates is explainable on the basis that the direct measurement method of obtaining blastocyst cell volume tends to over-estimate the cell volume (Table 1).

Discussion

Uptake of inositol by rabbit embryos was shown to increase slightly throughout the first 3 days of development and then increase markedly at the blastocyst stage; this increase was due almost entirely to the increase in embryo surface area at the blastocyst stage, as uptake of inositol by blastocysts was highly correlated with blastocyst diameter (\( r = 0.903 \)) and surface area (\( r = 0.851 \)). This finding is not surprising as the blastocyst largely consists of a sphere with a large cavity surrounded by a layer of trophoblastic or trophectodermal cells.
As blastocyst protein content is highly correlated \((r = 0.934)\) with surface area (Morgan and Kane, 1993), it is probable that inositol uptake is also highly correlated with blastocyst protein content.

At physiological concentrations of inositol in the incubation medium, the inositol uptake process in cleavage-stage rabbit embryos was mainly sodium dependent, saturable and inhibited by phloridzin, an inhibitor of sodium-dependent hexose transport, whereas the uptake process in blastocyst stages was non-sodium dependent and non-saturable. This situation is different from that in mice and cattle, the only other species examined to date, in which the uptake process is mainly sodium dependent in blastocyst stages (Kane et al., 1992; Hynes et al., 2000); uptake in cleavage-stage cattle embryos is also sodium dependent (Hynes et al., 2000) but the uptake mechanism in cleavage-stage mouse embryos depends on the stage of embryo (Higgins and Kane, 2003).

It is interesting to examine the change in inositol uptake per unit surface area from one-cell to blastocyst. It is possible to use the data for inositol uptake per embryo stage, assume a diameter of approximately 120 \(\mu\)m for the cellular portion of the one-cell and early morulae stages (Alliston and Pardee, 1973), take the measured values for the diameters of the early, mid- and late blastocysts, and from these data calculate the embryo surface area and the inositol uptake per \(cm^2\) (this cannot be carried out for the late morulae because the sizes of late morulae were not measured and sizes vary due to the start of embryonic growth at this time). The resulting uptake figures in pmol per \(cm^2\) are: one-cell embryo, 157 ± 18.8; early morulae, 243 ± 43.8; early blastocysts, 150 ± 9.0; mid-blastocysts, 115 ± 10.2; and late blastocysts, 107 ± 6.6. These results show that in spite of the marked change in mechanism of uptake from cleavage to blastocyst stages, the rabbit embryo maintains a relatively constant uptake of inositol per unit surface area at all stages of preimplantation development over a range of surface areas from 0.045 \(mm^2\) in the one-cell embryo to 22.6 \(mm^2\) in late blastocysts.

There is evidence from a wide range of tissues that the most common method of inositol uptake by cells is via a sodium-dependent, phloridzin-inhibitable, saturable cotransporter mechanism (for example, hamster intestine, Caspary and Crane, 1970; rat kidney, Whiteside et al., 1991). The responsible gene, the sodium myo-inositol transporter (SMIT) gene, which, in humans, is also called the SLC5A3 gene, has been cloned from cells from dogs (Kwon et al., 1992), cows (Zhou and Cammarata, 1997) and humans (Berry et al., 1995). The evidence in this paper indicates that expression of this gene may be responsible for inositol uptake in cleavage stages of rabbit embryos.

The \(K_m\) values for inositol uptake by early morulae (45 and 38 \(\mu\)mol \(l^{-1}\)) in the present study were within the physiological range of inositol concentrations (approximately 120 \(\mu\)mol \(l^{-1}\)) found in the oviductal fluid of the pregnant rabbit (Gregoire et al., 1962). Many sodium-dependent inositol transport systems have \(K_m\) values within the range 12–41 \(\mu\)mol \(l^{-1}\) (for review, see Garcia-Perez and Burg, 1991) but higher values have been reported, for example, 178 \(\mu\)mol \(l^{-1}\) in cultured renal epithelial cells (Russo et al., 1995). Assuming the protein content of the early rabbit morula is 0.29 \(\mu\)g (Morgan and Kane, 1993), the two \(V_{max}\) values from the results of the duplicate experiments presented in this study correspond to 783 and 993 pmol mg \(^{-1}\) protein per h. These values are within the range of \(V_{max}\) values found for other systems, for example, 56.8 pmol mg \(^{-1}\) protein per h for rat renal glomeruli (Whiteside et al., 1991) and 6060 pmol mg \(^{-1}\) protein per h for cultured rat fetal fibroblasts (Frueen and Lester, 1991). The report of \(K_m\) and \(V_{max}\) values for inositol transport in rabbit embryos in the present study is the first report of such values for inositol transport by the preimplantation embryos of any mammalian species.

In addition to the sodium-dependent mechanism of inositol uptake in cleavage-stage embryos in the present study, it is clear that there was also a sodium-independent mechanism of uptake which only became significant at high supra-physiological concentrations of inositol in the incubation medium. This ‘lipotropic’ (Holub, 1982; Wells, 1989) mechanism may be due to a very low solubility of inositol in the phospholipid layers of the membrane, which allows a limited diffusion across the plasma membrane. The magnitude of the sodium-independent uptake in cleavage stage embryos at physiological concentrations of inositol was probably over-estimated due to the presence of the sodium salts of pyruvate (0.5 mmol \(l^{-1}\)) and some amino acids in the sodium minus incubation medium.

Efflux of inositol from early morulae was minimal: about 1.25% of embryonic content per h compared with 15.6% for blastocyst stages. The mechanism of this low efflux in morulae may at least partly involve limited diffusion through the membrane. This limited efflux in early morulae indicates that under the conditions of the present experiments the sodium-dependent co-transport mechanism present in cleavage stages is functioning almost entirely in an inward direction.

The mechanism of the sodium-independent uptake in blastocyst stages remains unclear. It is unlikely to be the same mechanism as that responsible for sodium-independent transport in cleavage stages because of the great increase in sodium-independent transport necessary to maintain the relatively constant rate of uptake per unit surface area observed from cleavage to blastocyst stages. There is evidence in other tissues that sodium-independent inositol transport can take place via chloride channels (Reeves and Cammarata, 1996). In the present study, the effect of temperature on uptake of inositol by blastocyst cells and the fact that the process was not saturable up to a concentration of 50 mmol \(l^{-1}\) in the incubation medium is consistent with a channel
mechanism. One-cell mouse embryos have been shown to possess chloride channels (Kolajova and Baltz, 1999). The high rate of inositol efflux in blastocysts may take place via the same mechanism as influx. This contention is consistent with the fact that rates of inositol influx and efflux in blastocysts are broadly similar.

There is extensive evidence that inositol can function as an osmolyte which protects cells against osmotic stress; inositol can participate in either regulatory volume increase or decrease (RVI or RVD) in response to osmotic shock (for reviews, see Garcia-Perez and Burg, 1991; Lang et al., 1998). Mouse preimplantation embryo development has been shown to be inhibited by raised osmolality (Dawson and Baltz, 1997), and increased content of NaCl in the culture medium inhibits rabbit embryo development (Nagle et al., 1969). The expected response to hypertonicity of the incubation medium is an increased rate of inositol uptake as part of an RVI process (Burg, 1995). In the present study, incubation in media of varying osmolality for 40 or 120 min had no effect on inositol uptake by morulae. The results do not totally exclude such an effect of osmolality on cleavage-stage rabbit embryos as the incubation period may have been too short; the effect of hypertonicity on SMIT gene expression and inositol uptake in Madin–Darby canine kidney cells peaks at about 16 and 24 h, respectively (Yamauchi et al., 1993).

The expected response to hypotonicity of the incubation medium is an increased rate of inositol efflux as the cells reduce intracellular osmolality by effluxing osmolytes (RVD). Data from the present study showing a fivefold increase in inositol efflux in the low osmolality medium compared with the control medium provide clear evidence that this mechanism operates in rabbit morulae. There was a similar but much less marked effect of medium hypotonicity in blastocysts in the first 60–80 min after transfer to the hypotonic medium. One reason for the effect being less marked in blastocysts than in morulae may be that efflux may take place both into the blastocoel and the incubation medium. Although the mechanism of this hypotonicity-induced increase in inositol efflux is unknown, it may be similar, at least in cleavage-stage rabbit embryos, to the volume-regulated anion and organic osmolyte channels shown to operate in one-cell mouse embryos (Kolajova and Baltz, 1999; Baltz, 2001). There is one caveat to these and other inositol efflux studies: the possibility that the \(^{3}H\)inositol is metabolized to some other compounds which are effluxed from the cell in response to osmolality changes or that the tritium is transferred to another compound which functions as an osmolyte. However, \(^{3}H\)inositol is used extensively in studies of inositol efflux from cells and there appears to be little evidence in the literature of such problems being significant.

Transport across epithelial layers can occur via either a transcellular or a paracellular route (Stein, 1986). Results from the present study with intact blastocysts, which showed a much higher uptake of inositol per unit volume of blastocyst cells compared with blastocyst fluid after short-term (2 min) incubation with \(^{3}H\)inositol, indicate that uptake of inositol into the blastocyst takes place via a transcellular route, that is, inositol first passes into the outer trophectodermal layer of cells and then into the blastocyst fluid.

The change from a sodium-dependent mechanism of inositol transport to a sodium-independent mechanism at the morula to blastocyst transition is possibly related to the size and shape of the rabbit blastocyst. At implantation, rabbit blastocysts can have diameters of up to 6 mm (Alliston and Pardee, 1973), with a resulting low surface area to volume ratio and a large blastocoel. This cavity can readily act as a nutrient store. This nutrient store could facilitate the operation of a non-active transport system using a diffusion mechanism (possibly through channels) to transport some nutrients such as inositol. The diffusion mechanism could allow uptake by and efflux of inositol from the cells; however, much of the efflux could take place into the blastocyst cavity for later re-uptake into the blastocyst cells. Such a non-active process would have advantages over a sodium-dependent active transport system in terms of energy conservation. It is possible that this type of change in transport mechanism at the morula to blastocyst transition in rabbits may apply to compounds other than inositol.

The results from the present study provide a basis for the study of the phosphatidylinositol system in preimplantation rabbit embryos and illustrate the potential of the rabbit blastocyst as a model system for epithelial transport.
