There have been few studies on a possible maternal influence on in vitro embryo production in cows. The objective of this study was to evaluate the maternal influence on oocyte production and in vitro blastocyst formation rate using repeated ovum pick-up and in vitro fertilization. Six contemporary cows raised on the same farm and with varied genetic origins were submitted to 42 weeks of ovum pick-up organized into four series. Collected oocytes were fertilized in vitro with spermatozoa from a different bull for each series. In total, 1933 oocytes were recovered from 3936 follicles with a recovery rate of 57.2% and a mean oocyte collection of 4.6 ± 0.2 (mean ± SEM) per animal per session. Animals were ranked according to their oocyte production. The best oocyte donor was the same female in all four series. No relationship was identified between oocyte production and blastocyst production rate (r = −0.08). The mean blastocyst rate was 28.8% with significant variation among animals. The best and the worst blastocyst producers were always the same animals independent of the semen used. The results of the present study support the hypothesis that in cattle, the oocyte donor influences the production of blastocysts. Furthermore, they demonstrate that oocyte and embryo production are independent factors. Further studies are necessary to identify the maternal or oocyte factors responsible for such differences.

Introduction

The formation of normal embryos with the capacity to develop to term requires both oocyte and spermatozoa. Both parental components influence the characteristics of the newly formed embryo; however, the cytoplasm of the early embryo is composed almost entirely of the cytoplasm from the oocyte. As an important female contribution to embryonic development, the ooplasm contains elements necessary for early embryonic development and an intrinsic cytoplasmic programme that regulates early embryo development (Waksmundzka et al., 1984). This gamete anisogamy has imposed asymmetry on the inheritance of cytoplasmic factors resulting in a widespread predominance of maternal inheritance of organelles, proteins, RNA transcripts and other factors. This potential of the oocyte is best exemplified by the ability of the bovine ooplasm to reprogramme the nuclei of somatic cells creating a state of totipotency supporting embryonic development, as in cloning (Renard, 1998; Kikyo and Wolffe, 2000).

During their growth phase, oocytes undergo a marked increase in size due to the accumulation of cytoplasmic proteins, mRNA, organelles and other macromolecules that will be required for the initiation of development (Eppig, 2001). These maternally stored factors provide the necessary information for cell division during fertilization and the early stages of development. At this early stage, the induction of transcription inhibition does not prevent embryonic cleavage, indicating the total dependence of early development on maternal factors (for review, see Duranthon and Renard, 2003). These factors, which are stored in the oocytes, will sustain development from fertilization until the maternal–zygotic transition, which in cows occurs at the 16-cell stage (Telford et al., 1990; De Sousa et al., 1998). The importance of ooplasm inheritance is emphasized in the work of Renard et al. (1994) and Chastant et al. (1996) in which the source of oocyte cytoplasm affected blastocyst formation and gene expression.

In mice, both paternal (Shire and Whitten, 1980a) and maternal (Niwa et al., 1980; Shire and Whitten, 1980b; Renard et al., 1994) genetic factors have long been known to play a significant role in the time and rate of sperm penetration, fertilization, first cleavage, and blastocyst formation. Even though the large number of oocytes available from ovaries obtained from an abattoir facilitated the identification of paternal factors influencing bovine embryo production in vitro (Eid et al., 1994; Ward et al., 2001), the maternal influence has

1470-1626/2003
not been well documented. The paternal effect is seen at the first DNA replication cycle in which bulls with high blastocyst formation rate have longer replication cycles. These effects were not observed at fertilization or at the cleavage stage (Comizzoli et al., 2000). Conversely, studies that evaluate maternal influence on embryo production have been hampered for several reasons, among them the difficulty in obtaining large numbers of oocytes from the same female and the absence of inbred strains. The development of ultrasound guided follicular aspiration or ovum pick-up has proven to be a successful technique to collect oocytes repeatedly from live cows without affecting their future reproductive performance (Goto et al., 1988; Pieterse et al., 1988). This technique permits the production of oocytes that are genetically similar and allows comparative studies at the individual level to be performed.

In a large multiple ovulation embryo transfer retrospective study (1695 females and 2683 embryo collections), the maternal genetic ability to respond to superovulation was demonstrated (Govignon et al., 2000), as well as the contribution of recipient cattle to fertility after embryo transfer (McMillan and Donnison, 1999). Nevertheless, the maternal influence in oocyte production and on in vitro blastocyst production in cows remains undetermined. It was hypothesized that cows with varied genetic background have different capacities to produce oocytes by ovum pick-up and that their oocytes have different levels of competence for in vitro embryo production. The objective of this study was to estimate the variability between cows as oocyte donors and to identify different phenotypes for in vitro blastocyst formation.

Materials and Methods

Animals

Herd records were used to select six unrelated (that is without any common ancestor for at least two generations), contemporary, herd-mate Holstein cows as oocyte donors. They were all primiparous animals with similar milk. The animals received the same nutritional and health management from birth and throughout the experiment. These animals will be referred to in the text as animals C1–C6.

The ethical committee for experimentation with animals from the ENVA and from the INRA reviewed and approved the experimental protocol.

Experimental design

Ovum pick-up was performed over four series by the laboratory ovum pick-up team using standardized procedures. Oocytes collected during series 1, 2 and 3 were used for in vitro embryo production, whereas those from series 4 were used to evaluate fertilization rate. Semen from three different bulls (two Holstein and one Normand) was used for in vitro embryo production, one for each series. For the evaluation of fertilization rate (series 4) the spermatozoa used was the same as that of the first IVF series. Bulls were selected after testing the semen in IVF trials using oocytes recovered from ovaries obtained from an abattoir; only semen showing consistently high blastocyst rates was selected. Throughout the study, IVF was performed by three trained technicians using standardized procedures. After IVF, embryos were co-cultured in vitro and blastocyst formation was observed on day 8 after IVF.

Oocyte collection

Before the first ovum pick-up session, the oestrous cycles of the animals were synchronized using progestagen implants and prostaglandin F2α, as prescribed by the manufacturer (CRESTAR® method; Intervet, Angers). Oocyte collection was performed twice a week (Gibbons et al., 1994; Bungartz et al., 1995; Garcia and Salaheddine, 1998; Galli et al., 2001) on Monday and Thursday, starting 5 days after implant removal without any other additional hormonal treatment to stimulate follicular growth. Series 1–4 lasted 14, 13, 6 and 9 consecutive weeks, respectively. Follicular aspiration was performed as described by Pieterse et al. (1988). Cows were restrained in extension locks and a low epidural anaesthesia (5 ml of 2% lidocaine; Xylovet, CEVA Sante Animale, Libourne) was administered 10 min before ovum pick-up. Ovarian follicles were visualized using an ultrasound scanner equipped with a 7.5 MHz sectorial array transducer (Starvet 3, Pie Medical, Pouilly) placed in the cranial vagina and an 18-gauge short bevelled needle was used for follicular aspiration (Bols et al., 1996). Follicular contents were collected into a sterile 50 ml tube (one tube per animal) containing 10 ml of heparinized PBS (40 iu ml−1) and maintained at 37°C during the entire procedure. Once ovum pick-up was finished, the contents of the tubes were immediately filtered over a 100 µm mesh and rinsed with warm (37°C) PBS. Cumulus–oocyte complexes (COCs) were identified using a binocular stereoscope and transferred immediately into warm M199 supplemented with 10% fetal calf serum (FCS) (Life Technologies, Cergy).

Classification of COCs

COCs were classified according to their morphology into four categorical grades as described by de Loos et al. (1989) with some modifications as follows: (i) grade 1 (COC-1) corresponds to intact immature COCs with three or more layers of dense cumulus cells and homogeneous cytoplasm; (ii) grade 2 (COC-2) has fewer layers of compact cumulus investment or is a partially denuded oocyte with homogeneous cytoplasm; (iii) grade 3
In vitro maturation, fertilization and development

In vitro maturation and fertilization conditions were kept constant in the four experiments as described by Menck et al. (1997). The COCs graded 1, 2 and 3 from each animal were matured in vitro for 22–24 h into 50 µl microdrops (one microdrop for each oocyte donor) of M199 supplemented with 10% FCS, 10 µg FSH ml⁻¹, 10 µg LH ml⁻¹ and 1 µg oestradiol ml⁻¹ (Sigma, St Quentin-Fallavier), over a layer of Vero cells (Rhone-Mérieux, Lyon) to improve maturation of denuded oocytes (Grocholova et al., 1995). Oocytes from all six animals were processed at the same time, kept under a controlled atmosphere (5% CO₂ in air) and cultured in the same incubator.

After maturation, oocytes were fertilized in vitro (day 0) using frozen semen (same ejaculate) from a single bull. The spermatozoa from one thawed straw were selected by swim-up (Parrish et al., 1986) and each microdrop was inseminated to a final concentration of 1.0 x 10⁶ spermatozoa ml⁻¹. Presumptive zygotes were mechanically freed from their cumulus cells by gentle pipetting at 22 h after insemination. After rinsing, all oocytes exposed to spermatozoa were co-cultured in 50 µl microdrops of B2 medium (CCD, Paris) supplemented with 2.5% FCS containing a monolayer of Vero cells according to the routine used in the laboratory (Menck et al., 1997). Cleavage rate was observed at day 2 and blastocyst formation at days 6, 7 and 8.

Fertilization rate was specifically investigated with 18 additional ovum pick-up sessions in four animals which were selected based on their blastocyst production (series 4). The same maturation and fertilization techniques described above were used and oocytes were allowed to remain in the presence of spermatozoa for 13, 15 and 17 h before fixation. After fertilization, all presumptive zygotes were rinsed in M199 with 10% FCS and then fixed in 2.5% paraformaldehyde (Sigma) at room temperature for 15 min before they were rinsed in PBS and stored at 4°C overnight. DNA from the zygotes was stained with Hoechst 33342 (10 µg ml⁻¹, Sigma) in PBS at 39°C for 5 min. Zygotes were then mounted on glass slides with an anti-fading agent (Vectashield, Vector Laboratories, Abcys) for observation with an inverted microscope fitted for fluorescence and the presence and number of pronuclei were recorded.

Statistical analysis

Cows were compared for the number and percentage of oocytes recovered (series 1–4), fertilization rates (series 4), cleavage rate (number of cleaved embryos divided by the number of fertilized oocytes in co-culture) and blastocyst rate (in series 1–3 and defined as the number of blastocysts present at day 8 divided by the number of fertilized oocytes in co-culture). Cows were ranked using the Gabriel post hoc test by a comparison of means using ANOVA (SPSS release 10.0.1; SPSS Inc., Chicago). The model used included cow as the independent variable and the remaining variables as dependent variables. Pearson correlations among animals within- and between-experimental sessions for oocyte quality, cleavage rate and blastocyst rate were calculated as well as the oocyte recovery rate. Although ovum pick-up and IVF operators used standardized procedures throughout the experiment, they were also included in the model. All results are presented as mean ± SEM unless otherwise stated; values with different superscripts are statistically different (P < 0.05).

Results

Oocyte production (series 1–4)

Overall results. During the 42 weeks in which ovum pick-up was performed, 1933 oocytes were recovered from 3936 follicles with a mean recovery rate of 57.2% revealing a strong positive relationship (r = 0.4; P < 0.01). A mean number of 9.3 ± 0.2 follicles was aspirated with 4.6 ± 0.2 oocytes recovered per session per animal. From the recovered oocytes 82.1% were graded as COC-1 and -2, 10.1% as COC-3 and 7.8% as COC-4 (Fig. 1).

No differences among ovum pick-up operators were observed, although ovum pick-up was considerably more difficult in some cows.

Individual results. Individual mean oocyte production varied significantly in quantity but not in quality (proportion of each COC grade) among animals (Fig. 1). After ranking animals for oocyte production, it was observed that animal C5 had the lowest mean oocyte production whereas C2 had the best mean oocyte production per ovum pick-up session (Fig. 2). Cows were statistically ranked for oocyte production in each series and results showed that the statistical rank order remained virtually unchanged among the four series (Table 1). The number of oocytes recovered in each ovum pick-up session varied widely among animals, and the curves for most cows were non-symmetrical (skewness ± SEM = 0.3 ± 0.3, 1.2* ± 0.3, 0.8* ± 0.3, 0.7* ± 0.3, 1.1* ± 0.3, 0.6 ± 0.3 for cows C1–C6, respectively; *indicates deviation from normality). This is illustrated by the shape of the distribution curve and the standard deviation values (Figs 2 and 3). For each animal there was a significant positive
Fig. 1. Cumulative recovery rate of cumulus–oocyte complexes (COCs) for each cow (C1–C6) in experimental series 1–4. Columns represent the percentage of COCs of quality 1–4 (%COC-1; %COC-2; %COC-3; %COC-4) for each animal. The mean number of oocytes recovered for each animal, the average number of oocytes per ovum pick-up (OPU) session (±SEM) and the overall average of all animals are shown. Animals are ranked according to the number of oocytes recovered per OPU session.

correlation between the number of follicles aspirated and the number of oocytes recovered, except in animal C4 (r = 0.19).

Embryo production (series 1–3)

Overall results. Mean overall cleavage rate was 79.2% whereas the mean overall blastocyst rate was 28.8% (Table 2). A total of 532, 613 and 190 oocytes were fertilized in vitro in series 1, 2 and 3, respectively. The mean cleavage rate was 87.2%, 71.5% and 77.2%, with mean blastocyst rates of 35.8%, 19.8% and 31.1% for series 1, 2 and 3, respectively. Factors such as ovum pick-up operator and IVF technician did not significantly affect the results.

Fertilization rate. Overall, fertilization rate was 75.0% with the following individual rates: 66.7% (n = 24), 76.6% (n = 47), 73.9% (n = 46), 92.9% (n = 14) and 74.8% (n = 143) for animals C1, C2, C4, C5 and control, respectively. Fertilization rate did not differ among the four animals studied, independently of time of observation (13, 15 or 17 h after insemination). The overall rate of polyspermy was 5.1% and no animal differed significantly from this mean value.

Cleavage rate. Cleavage rates were not significantly different among the animals in all series (Table 3). Altogether, the number of recovered oocytes and cleavage rate showed a negative relationship (r = −0.13; P < 0.05); this was mainly due to animal C4, which was the only animal showing a significant correlation (r = −0.29; P < 0.05), whereas the other animals showed negative but non-significant correlations.

In vitro development: individual results. Cleavage and blastocyst rates for each female are presented (Table 2). No significant difference was observed for cleavage rate

Values in the same column with a different superscript are significantly different (P < 0.05). Animals are ranked on the basis of blastocyst production.

Fig. 3. Distribution of blastocyst formation rate from animals with extreme phenotypes for blastocyst production. Cow C4 and cow C5 were the worst and the best blastocyst producer, respectively. Bars represent the frequency of IVF sessions for blastocyst production (in intervals of 17%). The mean blastocyst production, the standard deviation and the total number of blastocysts produced in all three experimental sessions are shown.

among cows. When each series was analysed separately, the only significant difference found in cleavage rate was for series 3, in which animal C4 had a lower cleavage rate than animal C5 (57.5% versus 95.8%; P < 0.05, respectively). On the other hand, significant differences were observed for blastocyst rate between females, as indicated in Fig. 3, in which the blastocyst production profiles for the best and worst cows are represented.
When cows were statistically ranked according to blastocyst production, it was observed that the order remained practically the same in the three series (Table 3), whereby the best cow was always the best and the worst cow was always the worst producer of blastocysts in each series.

For all animals, no correlation was observed between the number of oocytes recovered and blastocyst production \( (\sigma = -0.08) \). On the contrary, cleavage rate and blastocyst rate showed a strong positive relationship \( (\sigma = 0.39; P < 0.01) \). Only animals C3 and C4 failed to show a significant relationship \( (\sigma = 0.29 \text{ and } \sigma = 0.17, \text{ respectively}) \). There was roughly a fourfold difference in the number of blastocysts per animal per IVF session between females (Table 2) ranging from 0.5 and 2.0 blastocysts per IVF session. Blastocyst formation rates of animals C1, C2 and C5 followed a normal distribution (skewness \( \pm \text{SEM} = 0.6 \pm 0.3, 0.6 \pm 0.3, \text{ and } -0.1 \pm 0.4 \)), whereas animals C3, C4 and C6 deviated from normality (skewness \( \pm \text{SEM} = 0.9 \pm 0.4, 1.5 \pm 0.3, 1.2 \pm 0.3 \)).

### Discussion

The present study was designed to evaluate the influence of the oocyte donor cow on the number of oocytes recovered and blastocyst formation rate using repeated ovum pick-up and IVF on the same cows, from different genetic origins. The data showed a distinctive variation in number of oocytes recovered by ovum pick-up per cow allowing the classification of some cows as systematically ‘good’ or ‘bad’ oocyte producers. The same effect was also observed for blastocyst production, with cows showing a phenotype of ‘good’ or ‘bad’ blastocyst producer. The semen used did not influence extreme phenotypes for blastocyst rate, revealing a maternal influence on bovine embryo development.

The oocyte recovery rate in the present study is consistent with the results reported by Garcia and Salaheddine (1998) but lower than those observed by Bungartz et al. (1995) and Bols et al. (1996). The number of aspirated follicles and oocytes recovered reported here were influenced by the presence of animals with different phenotypes for oocyte production, a phenomenon also observed by Kruij et al. (1994) and a factor observed in certain family lines (Bruggerhoff et al., 2002). Hasler et al. (1995) reported an animal-induced variation in the number of oocytes recovered as well as in the blastocyst rate, which was of a similar magnitude to the variations described above. Boni et al. (1997) identified a repeatable and predictable large variation in follicular recruitment between animals after several months of repeated ovum pick-up. The strong correlation found between the number of follicles aspirated and oocytes recovered in the present study leads the authors to believe that the variation in the quantity of oocytes recovered among animals is directly related to the variation in follicular recruitment. With the procedures described above, it was possible to successfully identify animals with different phenotypes (high, average or low) for oocyte production.

It is known that ovum pick-up conditions can influence the quality of the oocytes recovered (Kruij et al., 1994; Bols et al., 1996; Fry et al., 1997; Hashimoto et al., 1999). A significant variation in the quality of COCs recovered among animals was not observed in the present study; however, the vast majority of the COCs recovered were of good quality (grades 1 and 2). This absence of variation was due to the strict ovum pick-up conditions followed in each experiment and the small group of ovum pick-up technicians. The quality of the oocytes recovered by ovum pick-up also reflects the process of follicular recruitment and selection that eliminates faulty oocytes (Picton, 2001; Beg et al., 2002; Markstrom et al., 2002), although this effect is difficult to quantify because even a healthy follicle may contain an incompetent oocyte (Blondin and Sirard, 1995). As ovum pick-up was performed twice a week, the oocytes recovered were not subjected to the suppressive effects of a dominant follicle and oestrus and, therefore, were of good quality. Thus, the recovery of cumulus expanded oocytes or oocytes from atretic follicles was markedly reduced.

The animals that had high numbers of grade 1 and 2 oocytes did not have the expected higher blastocyst rates. This finding contradicts to some extent the observations made by Hashimoto et al. (1998) that developmental competence of bovine oocytes is induced in a cell.
density-dependent manner. This apparent difference can be explained by the origin of the oocytes. Whereas the present study used oocytes from the same animal, that is oocytes with the same cytoplasm and genetic background, Hashimoto et al. (1998) used oocytes recovered from ovaries obtained from an abattoir. This precluded the observation of individual animal effects, making COC morphology the only reliable variable to be considered. Furthermore, Boni et al. (2002) recently demonstrated that in cows, not only is morphological classification of COCs related to developmental competence, but also to other factors such as plasma membrane Ca\(^{2+}\) current (in the immature oocytes) and calcium stores (in mature oocytes). Tanghe et al. (2003) demonstrated that the maturation and fertilization rate of denuded oocytes are significantly improved if they are co-cultured in the presence of a monolayer of cumulus cells or placed in culture medium conditioned by the same cells. The role that the co-culture with Vero cells had in improving the maturation conditions of oocytes (mainly for single or denuded oocytes) is difficult to assess and is a potential variation factor.

The oocyte-origin effect over blastocyst production was not related to its ability to be fertilized, as observed by the high fertilization and cleavage rates obtained for all females. Nonetheless, a trend was observed: animals with high blastocyst production also had higher fertilization and cleavage rates than animals with a low blastocyst rate (data not shown). The maternal factors present in the ooplasm have direct effects on embryo fertilization and its kinetics (Renard et al., 1994; Duranthon and Renard, 2003) and they provide the oocyte with the molecules necessary in the control of embryonic development until the embryonic genome takes over (Telford et al., 1990; McCarthy and Ward, 2000; Miller, 2000; Oh et al., 2000). However, the spermatozoon should not be considered merely as a vector for paternal DNA as it carries a number of cytoplasmic factors that are essential for normal early fertilization (Wu et al., 1998; Knott et al., 2002). The observed variations in overall and individual mean blastocyst rates in all three series in which semen from different bulls was used clearly shows the paternal influence. This observed semen-induced variation is in agreement with that reported in the literature (Comizzoli et al., 2000; Ward et al., 2001). Comizzoli et al. (2000) did not observe a maternal genotype influence over time for onset of the first DNA replication in their work. Although the present study did not investigate the timing of onset of replication, the results show that the maternal influence is expressed during the later stages of development (no difference in fertilization and cleavage rate). Moreover, they used few randomly chosen females in their study; this might have masked the identification of females with different phenotypes, as could have been the case if fewer non-selected animals had been used in the present study. These sperm-induced variations only emphasize the maternal contribution as the best and worst blastocyst producers were always the same females.

The present data clearly show that the donor cow influences the quality of the oocyte, as measured by its ability to develop to the blastocyst stage in vitro. This is highlighted by the observation that the position of animals C4 and C5, when ranked for blastocyst rate in each experiment, was unchanged. In addition, animal C4 had a strong positively skewed distribution for blastocyst rate, indicative of a high incidence of IVF without blastocyst production. These differences may enable the development of a more rapid method for identifying animals with this phenotype. Animals with different blastocyst formation rates were also reported by Kruij et al. (1994) but they did not identify a maternal effect. At the present time, the heritability of the isolated phenotypes remains unknown and demands additional investigation, as there is evidence that it may be a transmissible characteristic (Bruggerhoff et al., 2002).

The number of blastocysts produced per ovum pick-up session was in the range achieved by others (Kruip et al., 1994; Hasler et al., 1995). However, in the present study it was observed that high oocyte production does not necessarily imply a higher blastocyst production rate but may result in a higher number of blastocysts. The lack of correlation between number of oocytes recovered and blastocyst rate shows the independence of the two factors measured. Moreover, the results showed that the animal with the best blastocyst rate was the worst oocyte producer; furthermore, this cow ranked third in total number of blastocysts produced. Meanwhile, the best oocyte producer had an average blastocyst rate making it the most productive cow. In short, when selecting animals for in vitro embryo production using the techniques described above, maximum yield will be achieved only if a compromise between selection for oocyte production and blastocyst rate is established.

At this point, it is not possible to identify the origin of this maternal effect as it could be of genetic, nuclear (Watson et al., 1999; Picton, 2001) or cytoplasmic origin (Cummins, 2001; Duranthon and Renard, 2003). The results of the present study support the hypothesis of a maternal influence on oocyte and blastocyst production in vitro. The selection of animals with different in vitro production phenotypes will permit comparative studies on the quantification of mitochondria in each oocyte and on the evaluation of mRNA and ATP, in an attempt to identify the origin of such differences in developmental competence.

The authors thank C. Shipley for his critical reading of the manuscript and comments. In addition, the authors gratefully acknowledge the help provided by the ovum pick-up technical team at the INRA experimental station of Bressonvilliers. This work was funded by the Biology of Reproduction laboratory at the Ecole Nationale Vétérinaire D’Alfort. A portion of the study was presented at the 17th reunion of the Association Européenne de Transfert Embryonnaire.
