Abstract

Homeobox genes encode transcription factors that have crucial roles in embryogenesis. A recently discovered set of homeobox genes – the *Rhox* genes – are expressed during both embryogenesis and in adult reproductive tissues. The 33 known mouse *Rhox* genes are clustered together in a single region on the X chromosome, while likely descendants of the primordial *Rhox* cluster, *Arx* and *Esx1*, have moved to other positions on the X chromosome. Here, we summarize what is known about the regulation and function of *Rhox* cluster and *Rhox*-related genes during embryogenesis and gametogenesis. The founding member of the *Rhox* gene cluster – *Rhox5* (previously known as *Pem*) – has been studied in the most depth and thus is the focus of this review. We also discuss the unusually rapid evolution of the *Rhox* gene cluster.

Reproduction (2010) **140** 195–213

Introduction

Homeobox genes encode transcription factors that govern a myriad of processes during development. They were first discovered over 25 years ago in *Drosophila melanogaster* and have since been identified in a wide variety of eukaryotic species. There are many subfamilies of homeobox transcription factors; all share a structurally conserved 60 amino acid DNA-binding homeodomain motif that recognizes specific DNA sequences (McGinnis & Krumlauf 1992). Homeobox transcription factors have critical roles in specifying spatial positioning of cells, controlling cellular proliferation, and regulating the differentiation of cells during embryonic development. Disruption or improper regulation of homeobox genes can result in drastic changes in developmental programs and elicit alterations in the identity of body segments. A striking example is the discovery that mutations in the fly *Antennapedia* homeobox gene cause transformation of the head segment into an abdominal segment that has a fully jointed leg in place of the antenna (Postlethwait & Schneiderman 1969). Such ‘homeotic transformations’ are a hallmark of many of the first discovered homeobox genes – the *Hox* genes – but they are not a universal feature of all homeobox genes. The only unifying feature of all homeobox genes is that they encode a homeodomain, a motif that binds not only to specific DNA sequences, but also to specific proteins, and sometimes even to RNA (Shyu & Wilkinson 2000, Svngen & Tonissen 2006).

This review focuses on the *Rhox* gene family, a recently discovered set of homeobox genes (MacLean *et al.* 2005a) clustered on the X chromosome (Fig. 1). As described in more detail in a later section, the mouse *Rhox* gene cluster harbors at least 33 genes and thus is the largest homeobox gene cluster known. Like most homeobox genes, *Rhox* genes are expressed during embryonic development (Fig. 2; Hogeveen & Sassone-Corsi 2005, MacLean *et al.* 2005a, Spitz & Duboule 2005, Zhan *et al.* 2005, Daggag *et al.* 2008). However, unlike most homeobox genes, *Rhox* genes typically remain expressed at high levels after birth, and thus are candidates to control postnatal and adult developmental events, particularly those essential for male and female reproduction (MacLean *et al.* 2005a). Some *Rhox* genes are expressed in germ cells, while others are expressed in somatic cells in the reproductive tract, including granulosa, Sertoli, and probably Leydig cells. Individual *Rhox* genes exhibit different, but sometimes overlapping, expression patterns. This suggests that each *Rhox* family member has the potential to have both unique and redundant roles in embryonic, postnatal, and adult development, a notion that is only beginning to be examined experimentally.

Here, we review what is known about the regulation, function, and evolution of the *Rhox* gene cluster, with an emphasis on the role and regulation of its family members in gametogenesis. We also refer readers to other reviews and commentaries covering *Rhox* genes (Lindsey & Wilkinson 1996a, Hogeveen & Sassone-Corsi 2005,

Figure 1 Organization of the *RhoX* cluster in rodents and humans. The syntenic region of the X chromosome containing the *RhoX* orthologs and conserved flanking genes is shown. The rodent *RhoX* gene subclusters are indicated by red (α), green (β), and blue (γ). Established orthologous genes are indicated by dotted lines. The orthologous relationship between human *RHOX* genes and rodent *RhoX* genes cannot be clearly assigned because of the rapid evolution of *RhoX* genes. The map positions shown are according to builds 37.1 (mouse), 3.4 (rat), and 37.1 (human).

MacLean & Wilkinson 2005, Spitz & Duboule 2005, Hu *et al.* 2007, Svingen & Koopman 2007, Shanker *et al.* 2008, Bettgowda & Wilkinson 2010).

RhoX5

RhoX5 (originally called *Pem*) was the first member of the *RhoX* gene cluster to be discovered. It was identified in a screen designed to find novel genes functioning in development and cancer. In particular, the screen identified *RhoX5* as being differentially expressed between two T-cell lymphoma clones from a common origin that were frozen at different developmental stages and had different malignant properties (Wilkinson *et al.* 1990). Subsequent work demonstrated that *RhoX5* is not only expressed in a subset of T-cell lymphomas, but it is widely expressed in tumors derived from many different cell types and tissue origins (Wilkinson *et al.* 1990, Maiti *et al.* 1996b, Wayne *et al.* 2002a). Its ubiquitous expression in tumors may derive, in part, from its ability to be induced by the *Ras* proto-oncogene (Rao *et al.* 2002a, MacLean *et al.* 2005b). *RHOX5* may also have a causal role in tumor formation, as it induces an immune response in mouse tumors (Ono *et al.* 2000), and it physically interacts with proteins involved in malignancy (Lemmens *et al.* 2001, Guo *et al.* 2005).

RhoX5 expression

While *RhoX5* was initially identified as being expressed in a T-lymphoma, it is not normally expressed in either the thymus or normal T cells (Wilkinson *et al.* 1990). Instead, it exhibits a highly selective and

developmentally regulated expression pattern during embryogenesis, postnatal development, and in adult animals. *RhoX5* is initially expressed in the unfertilized mouse oocyte, remains expressed at low levels in the blastocyst, and later is mainly confined in its expression to male and female primordial germ cells (PGCs) and extra-embryonic tissues, where it is expressed at very high levels (Wilkinson *et al.* 1990, Sasaki *et al.* 1991, Lin *et al.* 1994, Pitman *et al.* 1998, Hamatani *et al.* 2004, Chazaud *et al.* 2006, Daggag *et al.* 2008). After birth, its expression is primarily restricted to specific somatic cells in the reproductive tract: i) Sertoli cells in the testes, ii) principal cells in the epididymis, and iii) granulosa cells in the ovary (Wilkinson *et al.* 1990, Lin *et al.* 1994, Lindsey & Wilkinson 1996b, Maiti *et al.* 1996a, Pitman *et al.* 1998, Rao *et al.* 2002b). The expression of *RhoX5* in Sertoli cells is of interest given that these cells provide a structural framework for spermatogenesis and direct several androgen-dependent steps of spermatogenesis. Indeed, *RHOX5* expression in Sertoli cells is induced by androgen and AR and it is specifically expressed in Sertoli cells during the androgen-dependent stages (IV–VIII) of the spermatogenic epithelial cycle, making it a candidate to drive androgen-dependent steps of spermatogenesis (Lindsey & Wilkinson 1996c, Sutton *et al.* 1998, Rao *et al.* 2003). In the adult epididymis, *RhoX5* expression is restricted to the caput region, where sperm derived from the testis acquire forward motility (Rao & Wilkinson 2002, Rao *et al.* 2002b). In the adult ovary, *RHOX5* protein is exclusively in mural granulosa cells, which line the walls of the developing follicle and respond to the ovulatory LH surge (Pitman *et al.* 1998).

Figure 2 Summary of mouse *Rhox* cluster gene expression and function. The relative expression of each *Rhox* gene within the indicated tissue or cell type is shown by the heat map, with highly expressed genes shown in bright red and modestly expressed genes in maroon. The expression of *Rhox* genes in ES cells was determined by northern blot analysis (Sasaki *et al.* 1991, Fan *et al.* 1999), qPCR analysis (Jackson *et al.* 2002, Fouse *et al.* 2008), and semi-quantitative PCR analysis (Oda *et al.* 2006). The expression of *Rhox* genes in the early embryo (blastocyst to E8.5) was determined by semi-quantitative PCR analysis (Takasaki *et al.* 2000, Jackson *et al.* 2002, Chazaud *et al.* 2006); while *Rhox6* and *Rhox9* cannot be detected in normal mouse embryos, they can be detected in *Dnmt*-mutant embryos deficient in DNA methylation by RT-PCR (33 cycles; Oda *et al.* 2006). The expression of *Rhox* genes in fetal gonads was determined by qPCR and *in situ* hybridization analyses (Daggag *et al.* 2008); these analyses demonstrated that all *Rhox* genes are predominantly expressed in primordial germ cells (PGCs), except for *Rhox8*, which was exclusively expressed in gonadal somatic cells (s). 'm' and 'f' indicate expression specifically in male and female PGCs respectively. The expression of *Rhox1* to *Rhox12* in placenta and adult testes, epididymides, and ovaries was determined using qPCR analysis and/or ribonuclease protection analysis (MacLean *et al.* 2005a). The expression of *Rhox13* in ovary and testis was determined by northern and semi-quantitative RT-PCR analyses (Geyer & Eddy 2008); its expression in epididymis and placenta was determined by qPCR analysis (JA MacLean & MF Wilkinson 2007, unpublished observations). (*) *Rhox9* mRNA was reported as highly expressed in epididymis, but is now known to be an alternatively spliced *Rhox9* mRNA that generates an amino domain-truncated protein (JA MacLean & MF Wilkinson 2005, unpublished observations). *In vitro* and *in vivo* functional analyses of *Rhox5* were performed by Fan *et al.* (1999) and MacLean *et al.* (2005a), respectively. *In vitro* and *in vivo* functional analyses of *Rhox4* and *Rhox9* were performed by Takasaki *et al.* (2001) and Jackson *et al.* (2002), respectively.

Thus, RHOX5 is expressed in the nurse cells that translate the key hormone signal that promotes final oocyte maturation.

In vivo *Rhox5* functions

While analysis of its expression pattern allowed a speculative glimpse into *Rhox5*'s potential functions, it was not until the generation of *Rhox5*-null mice (Pitman *et al.* 1998) that its actual functions came to light. *Rhox5*-null males have increased germ cell apoptosis, reduced epididymal sperm count, reduced frequency of sperm with normal forward motility, and are subfertile (MacLean *et al.* 2005a). It is likely that the reduced sperm count results exclusively from the increased germ cell apoptosis, as cell proliferation (measured by bromodeoxyuridine incorporation) is not significantly affected by loss of *Rhox5*. Apoptosis is a normal event during spermatogenesis; it occurs specifically in a subset of spermatogonia and spermatocytes during stages I–IV and XII, respectively, of the seminiferous epithelial cycle. *Rhox5*-null males had higher numbers of apoptotic germ cells at these stages of the seminiferous epithelial cycle, indicating that RHOX5 is required for establishing the normal balance of germ cell survival versus death. In addition, *Rhox5*-null

males have apoptotic germ cells in stages of the seminiferous epithelial cycle that normally have none (i.e. stages V–XI). This 'promiscuous apoptosis' is intriguing because it suggests that RHOX5 has a role in specifying the stage-specific death cycle that normally occurs in spermatogenesis. RHOX5 is well placed to perform such a role, as it is specifically expressed in Sertoli cells, the central hub of the seminiferous epithelial cycle.

How exactly RHOX5 controls germ cell survival is not known, but it is likely to involve regulation of Sertoli cell genes encoding cell surface and secreted proteins that communicate with germ cells. As described in more detail below, several RHOX5-regulated genes encoding cell surface and secreted proteins that control cell survival and apoptosis have been identified (Hu *et al.* 2007, 2008; J MacLean II, Z Hu, M Rao, C Wayne & MF Wilkinson 2010, unpublished observations). By regulating such proteins, RHOX5 may be a major mediator of androgen action in the testes. Despite the well-established importance of androgens and testosterone in spermatogenesis, RHOX5 currently stands alone as an androgen-regulated transcription factor whose ablation results in abnormal spermatogenesis (MacLean & Wilkinson 2005, MacLean *et al.* 2005a, Hu *et al.* 2007, 2008). Because androgens act through the Sertoli

cells, not germ cells, to promote spermatogenesis (De Gendt *et al.* 2004, Holdcraft & Braun 2004, Chang *et al.* 2004, MacLean & Wilkinson 2005), this makes RHOX5 a strong candidate to have a role in one or more of the androgen-dependent steps of spermatogenesis.

The defect in sperm motility observed in *Rhox5*-null males could result from either an epididymal or a testes defect. The most likely site of the defect is the epididymis, as RHOX5 is specifically expressed in the caput region (Rao *et al.* 2002b), where sperm motility is acquired (Rao & Wilkinson 2002). However, it is possible that the defect is in the testes; in this case, the simplest explanation is that RHOX5 expression in Sertoli cells is necessary for the proper programming of the adjacent developing germ cells so that they are competent to later acquire motility in the epididymis.

The defects that have been detected in *Rhox5*-null mice are confined to the male reproductive tract. Thus, even though *Rhox5* is also expressed in granulosa cells in the ovary, *Rhox5*-null female mice have normal ovulation, litter frequency, and litter size (Pitman *et al.* 1998, MacLean *et al.* 2005a). Mice lacking *Rhox5* also have no obvious defects in embryonic development despite *Rhox5* normally being expressed in the early embryo, PGCs, and placenta (Pitman *et al.* 1998). One obvious explanation for this is that other *Rhox* family members compensate for the loss of *Rhox5*. Another non-mutually exclusive explanation is that *Rhox5*-null mice have subtle defects in embryonic development and female reproduction that have so far escaped detection. It is also possible that embryonic and female reproductive defects depend on context and would only be observed in particular environmental or genetic backgrounds. Finally, one cannot rule out that *Rhox5* expression in some cell types and developmental stages is 'noise' that has no functional significance; i.e. it has not been selected against because it is not deleterious.

While there is no *in vivo* evidence for an embryonic role of *Rhox5*, it is worth noting that Fan *et al.* (1999) showed that overexpression of RHOX5 in embryonic stem (ES) cells results in blockade of their differentiation *in vitro*. The differentiation block requires the amino terminus of RHOX5, not the homeodomain, suggesting that it might be the result of sequestering RHOX5-interacting factors crucial for ES cell differentiation. It will be interesting in the future to identify the RHOX5-interacting factors that have a role in this differentiation blockade.

Biochemical functions of RHOX5

When *Rhox5* was first identified, it was defined as a novel gene with no obvious motifs in common with other genes (Wilkinson *et al.* 1990). Thus, the biochemical function of its encoded protein was initially unclear. However, subsequent bioinformatic studies revealed that RHOX5

possesses a divergent homeodomain harboring the key amino acids necessary to form the homeodomain structure, but was otherwise substantially different than other homeodomains defined at that time (Rayle 1991, Sasaki *et al.* 1991). This was an important breakthrough for at least two reasons. First, it indicated that RHOX5 is almost certainly a transcription factor. Second, it suggested that RHOX5 might regulate sets of genes that are different than those regulated by other known homeobox proteins. Indeed, the RHOX5 homeodomain has unique amino acid residues at positions known to make base-specific contacts with DNA (Rayle 1991, Sasaki *et al.* 1991, MacLean *et al.* 2005a).

To begin to understand RHOX5's role as a transcription factor, two main approaches have been taken: i) the identification of genes regulated by RHOX5 and ii) the identification of proteins that interact with RHOX5. With regard to the first approach, Hu *et al.* (2010) conducted microarray analysis on 15P-1 Sertoli cell clones stably transfected with a *Rhox5* expression vector expressing physiological levels of RHOX5. This study identified many genes positively and negatively regulated by RHOX5 in 15P-1 cells; most of these are also regulated by RHOX5 *in vivo*, based on analysis of testes from *Rhox5*-null mice. Many of the RHOX5-regulated genes are expressed in Sertoli cells, indicating that they are candidates to be direct targets of RHOX5. A subset of these genes is regulated by androgen receptor (AR), suggesting that these are secondary androgen-response (SAR) genes; i.e. genes mediating testosterone signaling that are indirectly regulated by AR through the action of AR-regulated transcription factors. The best characterized SAR is *Unc5c*, which RHOX5 negatively regulates at the transcriptional level through the 5' UTR region of *Unc5c* (Hu *et al.* 2007, 2008). *Unc5c* encodes a netrin receptor that is crucial for axon guidance in the brain and is a tumor suppressor that promotes apoptosis (Arakawa 2004). To determine whether UNC5C also promotes apoptosis in the testes, Hu *et al.* examined *Unc5c*-null mice. They found that these UNC5C-deficient mice had reduced germ cell apoptosis (Hu *et al.* 2010), indicating that indeed UNC5C promotes the death of both germ cells and neurons. This discovery, coupled with the fact that RHOX5 negatively regulates *Unc5c* transcription (Hu *et al.* 2010) and promotes germ cell survival (MacLean *et al.* 2005a), supports a model in which the pro-survival activity of RHOX5 in the testis is mediated, in part, by its ability to repress the expression of the anti-survival gene *Unc5c*. Other Sertoli cell factors downstream of RHOX5 that may mediate germ cell survival have been identified by *in vivo* microarray analysis (Hu *et al.* 2007, J MacLean II, Z Hu, M Rao, C Wayne & MF Wilkinson 2010, unpublished observations). These factors include insulin and other secreted metabolic regulators, as well as key enzymes and transcription factors that control energy metabolism.

Homeodomain transcription factors do not act alone to regulate their target genes, but rather collaborate with other proteins. With this in mind, investigators have identified several proteins that interact with RHOX5, including menin (MEN1), prosaposin (PSAP), inhibitor of MyoD family (I-MFA; also known as MDFIC), and cell division cycle 37 (CDC37; Lemmens *et al.* 2001, Guo *et al.* 2005, 2007a, Luo *et al.* 2006). Interestingly, none of these are known transcriptional co-regulators, and thus their role in RHOX5-mediated transcriptional regulation is not yet clear. The best characterized of these proteins is menin, which is a nuclear protein with tumor suppressor activity that has been shown to interact with other transcription factors, including JunD (Lemmens *et al.* 2001, Poisson *et al.* 2003, and references therein). Two groups, Lemmens *et al.* and Poisson *et al.*, independently demonstrated that menin and RHOX5 directly interact, based on co-immunoprecipitation and GST-pulldown experiments in transfected cells. Lemmens *et al.* also showed that menin and *Rhox5* transcripts co-localize in seminiferous tubules, suggesting that the encoded proteins are normally co-expressed in the testes. However, it remains to be definitively determined whether menin protein is in Sertoli cells, the sole site of RHOX5 expression in the testis. Interestingly, menin has also been shown to interact with the homeobox transcription factor PDX1 in the pancreas to modulate the expression of insulin and insulin-like growth factor-binding protein 2 (La *et al.* 2006, Shen *et al.* 2009). This brings up the possibility that a RHOX5–menin interaction might also influence the expression of insulin-2 and other metabolism-related genes regulated by RHOX5 (J MacLean II, Z Hu, M Rao, C Wayne & MF Wilkinson 2010, unpublished observations).

Another protein that directly binds to RHOX5 is CDC37, a cell-cycle regulator that facilitates formation of the CDC28–G₁ cyclin complex (Guo *et al.* 2005). This suggests that RHOX5 and CDC37 might co-operate to promote cell proliferation, which is consistent with the fact that RHOX5 is expressed in highly proliferative cells, including trophoblasts and PGCs. If RHOX5 can only promote proliferation in cells that also contain CDC37, this would provide an explanation for why RHOX5 is also expressed in non-proliferative cells, such as post-mitotic Sertoli and epididymal cells, as these cells may lack CDC37. As part of its role in the cell cycle, RHOX5 may also function as a DNA checkpoint regulator. The evidence for this comes from the finding that transgenic mice overexpressing RHOX5 in Sertoli cells have increased DNA strand breaks in the adjacent germ cells during their maturation into elongated spermatids (Wayne *et al.* 2002b).

A third protein that has been shown to directly bind to RHOX5 is PSAP, a lysosomal enzyme activator that is necessary for the normal development of the testes and male accessory organs (Guo *et al.* 2007a). The notion that PSAP and RHOX5 collaborate is consistent with the

fact that both have known functions in the testis. However, it remains to be determined whether both normally exist in the same milieu, as RHOX5 is predominantly a nuclear protein, while PSAP is a cytoplasmic and secreted protein (Pitman *et al.* 1998, Rao *et al.* 2002b, Guo *et al.* 2007b). The cytoplasm may be a site where these two proteins interact, as RHOX5 has been shown to be present in the cytoplasm of some cells (Pitman *et al.* 1998, Rao *et al.* 2002b, 2003). By sequestering RHOX5 in the cytoplasm, PSAP may serve as a negative regulator of RHOX5's transcriptional functions in the nucleus.

Rhox5 evolution

As with perhaps the majority of proteins that function in the reproductive system (Swanson & Vacquier 2002), RHOX5 is rapidly evolving. Mouse and rat RHOX5 exhibit only 73% identity; the RHOX5 homeodomain region is even more divergent than the protein as a whole, displaying only 63% identity in mice and rats (Maiti *et al.* 1996b). This rapid evolution is not likely to be due to random drift; instead, evidence suggests that it is the result of positive selection pressure for alterations in amino acid sequence. The primary evidence for this comes from sequence analysis of a large panel of mouse and rat species, which showed that *Rhox5* has an extremely high ratio of non-synonymous-to-synonymous codon substitutions (Sutton & Wilkinson 1997a). Reinforcing the notion that positive selection is the driving force for this divergence was the finding that some *Rhox5* exons have undergone more rapid alterations in sequence than some *Rhox5* introns. The rate of *Rhox5* evolution is comparable with that occurring in the male-determining gene *Sry*, which encodes another transcription factor important for the male reproductive tract (Swanson & Vacquier 2002).

What selective forces have driven the rapid evolution of *Rhox5*? While the answer to this question is not known, it is worth first noting that even though the RHOX5 homeodomain as a whole has undergone a very high rate of sequence change, the sequences encoding two classes of amino acids within the RHOX5 homeodomain region have remained relatively intact. One class is the amino acids that are crucial for homeodomain structure and the other is the amino acids in the third helix, the 'recognition helix' that makes all the base-specific contacts with DNA (Sutton & Wilkinson 1997a). This suggests that purifying selection has fixed sequences crucial for maintaining both the RHOX5 homeodomain structure and its DNA targets. Why are the other amino acids in the RHOX5 homeodomain undergoing rapid change? Analysis of a large number of different homeobox transcription factors from different species has revealed that a common feature of their homeodomain region is that they bind not only DNA but also specific proteins (Moens & Selleri 2006). This leads

to the hypothesis that the rapid evolution of the RHOX5 homeodomain has been driven by the proteins with which it interacts. If true, it will be important to determine whether these are already identified RHOX5-interacting proteins or novel ones. It will also be intriguing to know whether the RHOX5 homeodomain has co-evolved with its binding partners over time or instead is undergoing selection to bind to new protein partners in different species.

Rhox5 regulation

The *Rhox5* gene is regulated by many different stimuli, including differentiation signals, oncogenic signals, hormones, and DNA methylation. Sasaki *et al.* (1991) was the first study to demonstrate that *Rhox5* is regulated by differentiation signals. These authors discovered that *Rhox5* mRNA levels are dramatically upregulated when ES cells are induced to differentiate into embryoid bodies, peaking 9 days after induction of differentiation. While they did not determine which specific cell types in differentiating ES cells express elevated levels of *Rhox5*, examination of the F9 embryocarcinoma cell line provided some insight into this issue. F9 cells are malignant but have stem-like qualities and thus they can be induced to specifically differentiate into visceral or parietal endoderm. Sasaki *et al.* (1991) found that F9 cells strongly upregulated *Rhox5* mRNA when they are induced to differentiate into either visceral endoderm or parietal endoderm. This recapitulates what occurs *in vivo*, as *Rhox5* is highly and specifically expressed in both the visceral and parietal endoderm components of the yolk sac (Wilkinson *et al.* 1990, Lin *et al.* 1994).

Rhox5 is regulated by DNA methylation

A regulatory mechanism that mounting evidence suggests is crucial for controlling *Rhox5* expression is DNA methylation. The first evidence for this was the finding by Sasaki *et al.* (1991) that treatment of mouse 10T $\frac{1}{2}$ mesenchymal stem cells with the DNA methyltransferase (DNMT) inhibitor 5-aza-2'-deoxycytidine (5AzaC) led to a dramatic (>50-fold) increase in *Rhox5* mRNA levels. *Rhox5* mRNA was specifically induced in 10T $\frac{1}{2}$ derivatives that committed to the muscle cell lineage (myoblasts), not to cells that committed to the cartilage (chondrocyte) or fat cell (adipocyte) lineages. This induction may be physiologically relevant, as *Rhox5* transcripts, including a muscle-specific alternatively spliced form, are expressed at modest levels in rat skeletal muscle (Maiti *et al.* 1996a). However, *Rhox5* mRNA is not detectably expressed in mouse skeletal muscle (MacLean *et al.* 2005a), indicating that if indeed *Rhox5* does have a role in muscle differentiation, it is not a conserved role.

Another interpretation of the observation that *Rhox5* is dramatically induced by chemical inhibition of DNA

methylation in muscle cells is that this reflects *Rhox5* being transcriptionally repressed by DNA methylation in inappropriate cell lineages. Two subsequent studies – both of which employed genetic manipulation techniques to knockout genes encoding DNMTs – obtained evidence that indeed this is the case. Jackson-Grusby *et al.* used microarray analysis to identify genes upregulated in cultured fibroblasts that lack DNMT1, the 'maintenance DNMT' essential for maintaining heritable DNA methylation patterns in dividing cells. *Rhox5* was one of the most upregulated genes (by ~14-fold) identified in these DNA methylation-deficient cells (Jackson-Grusby *et al.* 2001). Given that *Rhox5* is not normally expressed in fibroblasts, this provided evidence that DNA methylation is sufficient to prevent its expression in this cell type. However, it did not rule out that DNA demethylation triggers other events, such as changes in histone modifications, which contributed to the derepression of *Rhox5* transcription.

Oda *et al.* (2006) examined whether DNA methylation is responsible for preventing *Rhox5* expression in mid-gestation embryos. Consistent with this, they observed that the *Rhox5* promoter shifts from being in an unmethylated state in eight-cell embryos and blastocysts – both of which express *Rhox5* – to a methylated state in mid-gestation (e8.5) embryos, which lack detectable *Rhox5* expression (Lin *et al.* 1994, Hamatani *et al.* 2004). It should be noted, however, that Oda *et al.* examined the methylation status of the *Rhox5* alternative promoter not appreciably expressed in early embryos (Rao *et al.* 2003; see next section for a description of the alternative *Rhox5* promoters). To obtain direct evidence for a role of DNA methylation, Oda *et al.* examined the effect of loss of DNMT3a and DNMT3b, the 'de novo synthesis DNMTs' that are responsible for new DNA methylation events in ES cells, trophoblast tissues, and PGCs (Okano *et al.* 1999). Mice lacking both of these enzymes fail to produce viable offspring, exhibit abnormal growth rate and development, and die prior to e11.5 (Okano *et al.* 1999). They found that *Dnmt3a*^{-/-}*Dnmt3b*^{-/-} e8.5–9.5 embryos harbor a hypomethylated *Rhox5* gene promoter that is derepressed, allowing high levels of *Rhox5* transcripts to be expressed. The repression of *Rhox5* expression in early embryos can be mediated by either of the *de novo* synthesis DNMTs, as single-mutant (*Dnmt3a*^{-/-} or *Dnmt3b*^{-/-}) embryos did not exhibit a detectable increase in *Rhox5* mRNA expression. Surprisingly, single-mutant *Dnmt3b*^{-/-} embryos did exhibit reduced *Rhox5* promoter DNA methylation. This suggests that either i) DNA demethylation is not sufficient for *Rhox5* transcription, ii) a threshold of reduced DNA methylation is required to activate *Rhox5* transcription, or iii) DNA demethylation triggers only a modest increase in *Rhox5* transcription that was not detected by the investigators.

In contrast to the embryo proper, extra-embryonic tissues constitutively express high levels of *Rhox5*

(Wilkinson *et al.* 1990), which was not significantly further increased by loss of DNMT3a and DNMT3b (Oda *et al.* 2006). Together with an earlier report that found that *Rhox5* is selectively hypomethylated in placenta (Schutt *et al.* 2003), these data collectively indicate that DNA methylation defines the tissue-specific expression pattern of *Rhox5* by virtue of its ability to prevent *Rhox5* expression in mid-gestation embryos. In the future, it will be interesting to determine whether the induction of *Rhox5* expression in PGCs in later-stage embryos (Pitman *et al.* 1998, Daggag *et al.* 2008) is the result of cell type-specific DNA demethylation.

***Rhox5* is an imprinted gene**

DNA methylation controls genomic imprinting, an epigenetic process that results in the selective repression of one of the two alleles of a given gene. Paternally imprinted genes are methylated and transcriptionally silenced on the paternal allele, whereas maternally imprinted genes are methylated and transcriptionally silenced on the maternal allele. Genomic imprinting acts only on a selected subset of genes (<100 are known in humans and mice), and its evolutionary origin and functional importance – while under intense investigation – remain unclear (Moore 2001, Laprise 2009). Imprinting would seem to put organisms at a disadvantage since it causes genes to be functionally haploid, and thus it increases the risk that mutations in them will lead to phenotypic defects. Genomic imprinting may have evolved as a result of selection pressure arising from opposing needs of the two parental genomes; the paternal genome selects for features that promote placental and prenatal growth, while the maternal genome selects for features that conserve resources and thereby reduce growth.

Recently, *Rhox5* has been demonstrated to be a gene imprinted in the early embryo. This was uncovered by Kobayashi *et al.* (2006) whose initial goal was to identify genes differentially expressed in male and female blastocysts. Using offspring from male mice that harbored a green fluorescent protein (GFP)-expressing transgene on their X chromosome, these authors sorted GFP-expressing female and non-expressing male blastocysts and found – using expression profiling – that ~600 genes were differentially expressed by twofold or more, with roughly half being expressed at higher levels in female blastocysts and the other half being preferentially expressed in male blastocysts. Of those preferentially expressed in female blastocysts, only two genes were found to be exclusively in female blastocysts: *Xist* and *Rhox5*. The finding that *Xist* was exclusively expressed in female blastocysts was expected, as it is a non-coding transcript specifically expressed in female cells that is crucial for X-chromosome inactivation and dosage compensation in female cells (Chow & Heard 2009). The discovery that *Rhox5* exhibits

a female-specific expression pattern was unexpected; subsequent investigation revealed the reason: *Rhox5* is exclusively expressed from the paternal X chromosome (Kobayashi *et al.* 2006), which is not present in male blastocysts. The authors went on to show that the paternal-specific expression of *Rhox5* is established by the eight-cell stage and is maintained until e6.5.

It remains for future investigations to understand the mechanism and functional significance of *Rhox5* imprinting in the early embryo. As described earlier, *Rhox5* controls the expression of several genes regulating energy metabolism, including those encoding secreted proteins and master transcriptional regulators that are likely to influence large batteries of downstream energy metabolism genes (Hu *et al.* 2007). This suggests the possibility that *Rhox5* is subject to imprinting because of competition between male and female early embryos for limited energy resources. Because *Rhox5* is on the X chromosome, it may also be subject to another form of imprinting. Most X-linked genes are preferentially expressed from the maternal allele in extra-embryonic tissue as a result of a chromosome-wide paternal imprinting mechanism (Reik & Lewis 2005). While Kobayashi *et al.* (2006) did not address whether *Rhox5* is subject to this mechanism, they did obtain evidence that e7.5 embryos express higher levels of *Rhox5* from the maternal allele than from the paternal allele, consistent with this possibility. Furthermore, two X-linked *Rhox5*-related genes, *Rhox6* and *Esx1*, have been shown to be paternally imprinted in extra-embryonic tissue (Li & Behringer 1998, Oda *et al.* 2006). To directly address this issue, we examined placental tissue from crosses of two related species with recognizably different *Rhox5* alleles (*Mus musculus musculus* and *Mus musculus molossinus*) and found that *Rhox5* was preferentially expressed from the maternal allele, regardless of its species of origin (J MacLean II, Z Hu, M Rao, C Wayne & MF Wilkinson 2010, unpublished observations). Coupled with the work of Kobayashi *et al.* (2006), this demonstrates that *Rhox5* is an unusual gene that is paternally imprinted in extra-embryonic tissues and maternally imprinted in the early embryo. Few other mammalian genes are known to be both paternally and maternally imprinted; it will be interesting to know the functional consequences of this unique expression pattern. It will also be important to determine whether *Rhox5* undergoes a switch in imprinting (from paternal to maternal) in some cell types or instead undergoes different kinds of imprinting (maternal or paternal) in different cell types.

Because *Rhox5* has roles in spermatogenesis (MacLean *et al.* 2005a), it will also be important to know whether *Rhox5* imprinting pattern has consequences for male fertility. Indeed, abnormalities in both maternal and paternal imprinting have been associated with low sperm quality and hypofertility in humans (Kobayashi *et al.* 2007, Marques *et al.* 2010).

Furthermore, human sperm harboring genes that are abnormally imprinted have been shown to be less likely to be competent for IVF and ICSI (Kobayashi *et al.* 2007). Thus, it will be interesting to determine whether human *RHOX* genes are subject to imprinting and, if so, whether *RHOX* imprinting abnormalities have a negative impact on human fertility.

Rhox5 has two promoters

Rhox5 mRNA is transcribed from two promoters that are independently regulated but give rise to the same protein. The proximal promoter (*Pp*) is of interest because it is directly regulated by the nuclear hormone receptor AR, which along with other transcription factors restricts its expression to specific somatic cell types in the testes and epididymis. The distal promoter (*Pd*) is also expressed in a tissue- and cell type-specific manner, but its primary sites of expression are in the early embryo and somatic cells in adult female reproductive tissues. The *Pd* is also expressed in a wide variety of tumors. In this section, we describe the expression pattern of these two promoters in more detail, and then review studies that have examined the *cis* elements and *trans*-acting factors that control their unique expression patterns.

The Pp

The *Pp* gives rise to full-length mRNA specifically in the testis and epididymis in both mice and rats (Maiti *et al.* 1996a, 1996b, Sutton *et al.* 1998, Rao *et al.* 2003). In mice testes, where *Pp*-derived transcripts are dramatically induced between P8 and P9, *Pp* expression is restricted to Sertoli cells (Lindsey & Wilkinson 1996c, Sutton *et al.* 1998, Rao *et al.* 2003). *Pp* expression is further restricted to Sertoli cells in stages IV–VII of the seminiferous epithelial cycle in adult mouse testes, as *Rhox5* mRNA and RHOX5 protein are only observable in these stages (Lindsey & Wilkinson 1996c, Sutton *et al.* 1998, Rao *et al.* 2003). In the mouse epididymis, the *Pp* is specifically expressed in somatic cells (primarily in principal cells) in segments 2–4 of the caput region (Rao *et al.* 2002b). Together, these data indicate that the *Pp* is an exquisitely regulated promoter that is expressed in a cell type-, region-, stage-, and tissue-specific manner.

Pp transcription in both the testes and epididymis depends on AR and testosterone. This conclusion comes from several lines of evidence, including: i) *Rhox5* mRNA levels (measured with either *Rhox5* or *Pp*-specific probes) are dramatically reduced in animals deficient in the ability to produce LH (the peptide hormone responsible for inducing testosterone production in Leydig cells) as a result of hypophysectomy, chemical treatment, or genetic mutations (Lindsey & Wilkinson 1996b, 1996c, Maiti *et al.* 1996a, Sutton *et al.* 1998); ii) testosterone reverses the defect in *Rhox5* expression

caused by loss of LH (Lindsey & Wilkinson 1996b); iii) androgens induce *Rhox5* and/or *Pp*-driven reporter expression in primary Sertoli cell cultures and Sertoli cell lines (Rao *et al.* 2003, Sneddon *et al.* 2005, Zhou *et al.* 2005); iv) AR-deficient mice have reduced testicular *Rhox5* expression (De Gendt *et al.* 2004, Holdcraft & Braun 2004, Tan *et al.* 2005, O'Shaughnessy *et al.* 2007, Schauwaers *et al.* 2007); v) *Rhox5* expression is drastically reduced in testes lacking AR specifically in Sertoli cells (De Gendt *et al.* 2004, Holdcraft & Braun 2004, Denolet *et al.* 2006); vi) *Rhox5*, as well as some other androgen-dependent genes, exhibits modestly reduced expression in mice lacking AR in peritubular myoid cells and smooth muscle cells, suggesting that AR can also exert effects on Sertoli cells indirectly; vii) *Rhox5* has been shown to be positively regulated by AR and/or androgen in several independent expression profiling (microarray) studies conducted in different model systems in both mice and cell lines (Sadate-Ngatchou *et al.* 2004, Zhou *et al.* 2005, Denolet *et al.* 2006, Eakin & Hadjantonakis 2006, Kobayashi *et al.* 2006, Eacker *et al.* 2007, O'Shaughnessy *et al.* 2007, Prante *et al.* 2008, De Gendt *et al.* 2009); viii) RHOX5 is localized to Sertoli cells specifically during the androgen-dependent stages of spermatogenesis (Lindsey & Wilkinson 1996b, Sutton *et al.* 1998); and ix) the *Pp* possesses four androgen-response elements (AREs), each of which is required for its AR- and androgen-dependent expression in transfected cell lines (Barbulescu *et al.* 2001, Geserick *et al.* 2003, Bhardwaj *et al.* 2008, Faus & Haendler 2008). Together, these studies strongly suggest that the *Rhox5 Pp* is a direct target of AR in Sertoli cells.

The highly androgen/AR-dependent expression of *Rhox5* has led to *Rhox5* being widely used as a marker to examine perturbations disturbing androgen signaling (Sutton *et al.* 1998, Barbulescu *et al.* 2001, Geserick *et al.* 2003, De Gendt *et al.* 2004, MacLean & Wilkinson 2005, Terada *et al.* 2005, Bhardwaj *et al.* 2008, Prante *et al.* 2008). Because the *Rhox5* gene encodes a transcription factor, another implication of its androgen/AR-dependent expression is that it is a candidate to regulate the transcription of genes that mediate androgen action during spermatogenesis (MacLean & Wilkinson 2005). Indeed, as described earlier, RHOX5 controls the expression of several AR-regulated genes (Hu *et al.* 2010). To date, no other androgen- and AR-inducible transcription factors have been identified in Sertoli cells.

Analysis of transgenic mice harboring different lengths of *Pp* 5' upstream sequences by Rao *et al.* (2002b, 2003) revealed that all of the elements necessary for androgen-dependent and cell type-specific expression of *Rhox5* are present within the first ~600 nt upstream of the *Pp* transcription start site. This sequence is divided into two ~300 nt regulatory domains: regions I and II. Region I contains one or more repressor elements that dictate, at least in part, the specificity of *Pp* expression. In the testis, region I helps confer the stage-specific expression of

Rhox5 during seminiferous epithelial cycle (Lindsey & Wilkinson 1996b, 1996c, Sutton *et al.* 1998) by inhibiting *Pp* expression in other stages (Rao *et al.* 2003). In the epididymis, region I inhibits inappropriate expression of the *Pp* in epididymal regions other than the caput (Rao *et al.* 2002b).

Region II confers the other properties of the *Pp*, including its i) androgen-dependent expression, ii) tissue-specific expression in the testis and epididymis, and iii) Sertoli cell-specific expression in the testes (Rao *et al.* 2002b, 2003). Androgen-dependent expression is conferred by the four AREs in region II (Barbulescu *et al.* 2001, Geserick *et al.* 2003, Bhardwaj *et al.* 2008). These AREs also contribute to the tissue- and cell type-specific expression pattern of the *Pp*, as recently shown by Bhardwaj *et al.* (2008). Consensus AREs have also been identified in the *Rhox5*-related human *RHOXF2A* gene (Wayne *et al.* 2002a), but to date, AR-dependent expression has only been demonstrated for the *RHOXF1* gene (Geserick *et al.* 2002).

Bhardwaj *et al.* (2008) also identified other *cis* elements in region II that collaborate with AREs to drive cell type-specific expression. Most importantly, they identified several GATA transcription factor-binding sites crucial for the expression of the *Pp* in Sertoli cells, at least one of which is crucial for *Pp* transcription *in vivo*. This conclusion is based on several lines of evidence, including: i) mutation of the GATA consensus sites in region II reduces *Pp* transcription in transiently transfected Sertoli cells, ii) mutation of the GATA site most crucial for *Pp* expression in transfected cells also strongly reduces *Pp* expression in transgenic mice, iii) forced expression of GATA factors, in combination with AR, induces *Rhox5* expression in Sertoli cell lines that constitutively express low levels of the GATA factors, iv) this ability of GATA factors to increase *Pp* expression is abrogated by mutation of the crucial GATA site important *in vivo*, and v) several GATA factors are recruited to the *Pp* in adult testes and the MSC1 Sertoli cell line, as shown by chromatin immunoprecipitation (ChIP) analysis.

The induction of *Pp* expression by GATA transcription factors is likely to depend on their ability to co-operate with AR (Bhardwaj *et al.* 2008). An indirect line of evidence for this is that the GATA site crucial for *Pp* transcription *in vivo* is <25 nt from two AREs in region II. More compelling evidence is that GATA factors and AR form a complex *in vitro*. Depletion of either GATA-binding site factors or ARE-binding factors ablates the formation of this complex. Furthermore, forced expression of GATA transcription factors rescues expression from *Pp* reporter constructs harboring mutations in any of the four AREs in region II. Finally, the level of GATA factors bound to the *Pp* (as measured by ChIP) in MSC1 cells is increased in response to the addition of AR and androgen.

It remains for future studies to determine which of the six known GATA transcription factors are responsible for co-operating with AR to induce *Pp* expression. GATA1 is one candidate, as *Gata1* mRNA levels increase concomitantly with *Ar* and *Pp* mRNA levels during postnatal testis development (Bhardwaj *et al.* 2008). Other candidates are GATA4 and GATA6, as they are expressed at high levels in Sertoli cells (Viger *et al.* 2008). However, *Gata4* and *Gata6* mRNAs are downregulated during postnatal testes development (Bhardwaj *et al.* 2008), suggesting that their role in regulating *Pp* might primarily be in the early portion of the first wave of spermatogenesis. Of the other three GATA factors, only GATA2 is significantly expressed in Sertoli cells (Bhardwaj *et al.* 2008), making GATA2 another candidate to regulate *Pp* transcription. This notion is supported by the finding that GATA2 is bound to the *Pp* in both the adult testes and the MSC1 Sertoli cell line (Bhardwaj *et al.* 2008).

Restriction of *Pp* expression to Sertoli cells is conferred not only by transcription-promoting factors but also by negative regulatory influences. While not well defined, region II appears to have a repressor element that inhibits *Rhox5* expression in non-Sertoli cells (Bhardwaj *et al.* 2008). In addition, as described above, a regulatory region resides upstream of this element – within region I – that represses *Pp* expression in Sertoli cells in stages of the seminiferous epithelial cycle that normally do not express *RHOX5* (Rao *et al.* 2003). The putative inhibitor factors that confer negative regulation by binding to these inhibitory elements in regions I and II have not yet been identified.

The *Pd*

The *Pd* is expressed in the ovary and placenta, and is also co-expressed with the *Pp* in the testes (Maiti *et al.* 1996a, 2001, MacLean *et al.* 2005b). The likely cellular site of *Pd* expression in the ovary is mural granulosa cells, as that is where *RHOX5* protein has been shown to be specifically expressed (Pitman *et al.* 1998). The *Pd* is broadly expressed in the placenta, based on the finding that *RHOX5* protein is present in spongiotrophoblasts, labyrinthine trophoblasts, and trophoblast giant cells (Lin *et al.* 1994, Pitman *et al.* 1998). The *Pd* is also responsible for expression of *Rhox5* in the embryo proper and ES cells (Rao *et al.* 2003; A Bhardwaj & MF Wilkinson 2009, unpublished observations). In contrast to its highly specific expression in normal tissues, the *Pd* is widely expressed in tumors, regardless of cell lineage or tissue of origin (Wilkinson *et al.* 1990, Rao *et al.* 2002a).

A minimal element required for *Pd* transcription has been defined (~100 nt upstream of its transcription start site) that is only 22 nt in length (Rao *et al.* 2002a, MacLean *et al.* 2005b). This 22-nt element is sufficient to activate the transcription of an inactive heterologous promoter in primary granulosa cells and tumor cells. It consists of two ETS family-binding sites and a single SP1

family-binding site. One ETS family member, GABP, and two SP1 family members, SP1 and SP3, have been shown to act through these binding sites to activate *Pd* transcription, based on the following lines of evidence: i) overexpression of any of these three transcription factors elicits a dose-dependent increase in *Pd* expression in primary mouse or rat granulosa cells; ii) dominant-negative forms of these transcription factors decrease *Pd* transcriptional activity; iii) all three of these transcription factors bind to the *Pd*, as assessed by EMSA analyses, and iv) mutation of any one of the binding sites for these three factors reduces *Pd* transcription. In the future, it will be important to determine whether other members of the large ETS family besides GABP control *Pd* transcription. The ETS family member ELF1 binds to the *Pd*, but its functional role in *Pd* transcription is not known (Rao *et al.* 2002a). Interestingly, ELF1 upregulation has been associated with gynecological cancers of the cervix, uterus, and breast (Andrews *et al.* 2008, Nicol *et al.* 2008), but whether it has a role in ovarian tumors has not been determined. It will also be important to determine whether the *Pd* minimal element drives *Rhox5* expression in cell types besides primary granulosa cells and tumor cells.

Because the processes of ovulation and tumorigenesis are both induced and propagated by related receptor-mediated signal transduction events via growth factors and inflammatory cytokines, it is perhaps not surprising to find that the *Pd* is transcriptionally activated by such signaling events. A key signal transduction event required for *Pd* transcription is initiated by the G-protein RAS (Rao *et al.* 2002a, MacLean *et al.* 2005b). Gain-of-function evidence for this is that transient transfection of a constitutive form of RAS induces *Pd* expression in primary granulosa cells, mesenchymal stem cells, and tumor cells. Conversely, a dominant-negative form of RAS inhibits *Pd* transcription in both primary granulosa cells and tumor cells. The ability of RAS-mediated signaling to induce the *Pd* in granulosa cells is interesting in light of the fact that the LH surge that triggers ovulation activates K-RAS in granulosa cells (Fan *et al.* 2008). K-RAS signaling is also required for the phosphorylation and activation of MAPK3/1 (ERK1/2), which, in turn, is required for granulosa cells to promote LH-induced resumption of germ cell meiosis, ovulation, and luteinization (Fan *et al.* 2009). Gonadotropin treatment induces peak MAPK3/1 activity in rodent granulosa cells at a similar time point as that for maximal *Pd* mRNA levels (MacLean *et al.* 2005b, Fan *et al.* 2009), suggesting the possibility that *Pd* transcription also requires MAPK3/1. While this has not been tested, it is known that other components of the MAP kinase pathway – namely the stress-activated protein kinase/c-Jun amino-terminal kinases – are required for *Pd* transcription (Rao *et al.* 2002a, MacLean *et al.* 2005b).

The finding that RAS signaling activates the *Pd* strongly suggests that RAS transformation is responsible for the expression of *Rhox5* in a broad array of tumor cells. Furthermore, because RAS is known to stimulate the activity of SP1 and ETS factors (Kivinen *et al.* 1999, Yordy & Muise-Helmericks 2000), this provides an obvious mechanism for how RAS induces *Pd* transcription. While RAS activation typically occurs as a result of mutation in tumor cells, it remains unclear what activates RAS in normal cells. The identification of upstream factors, including extracellular factors, which activate RAS in granulosa cells and other cell types, will be an important future goal for the field.

Further insights into the regulation of *Pd* transcription have come from a recent study by Li *et al.* (2009) who used 'epigenetic' inhibitors to study the role of DNA methylation and histone modifications in regulating the *Pd*. The drugs used by the investigators were the DNMT inhibitor 5AzaC, the histone deacetylase inhibitor MS-275, and the chemotherapeutic drug arsenic trioxide (ATO), all of which trigger both DNA demethylation and histone modifications favorable for transcription. They found that all three drugs induced *Pd*-derived transcripts in several different cell lines. ATO and MS-275 induced only *Pd*-derived transcripts, not *Pp*-derived transcripts, consistent with other studies showing that these two promoters are independently regulated. Interestingly, even though these two inhibitors decreased global DNMT levels, they did not lead to significant demethylation of the *Pd*, suggesting that these inhibitors induced the *Pd* by a DNA methylation-independent mechanism. Indeed, both inhibitors elicited transcription-promoting histone modifications at the *Pd*. 5AzaC was unique in its ability to induce both *Pd*- and *Pp*-derived transcripts. It probably acted by directly demethylating these promoters, as both the *Pd* and *Pp* underwent a dramatic decrease in methylation in response to 5AzaC. This is probably also the mechanism responsible for the dramatic induction of *Rhox5* transcripts in 10T $\frac{1}{2}$ mesenchymal stem cells reported earlier (Sasaki *et al.* 1991). However, 5AzaC treatment also increased the levels of transcription-promoting histone modifications at the *Pd*, complicating the interpretation of its mechanism of action (Li *et al.* 2009). In the future, it will be important to untangle the independent contributions of DNA methylation and histone modifications, a challenging task given that these two events are intimately linked at many levels (Berger 2007).

Rhox5 is not alone on the X chromosome

Rhox5 is not an orphan homeobox gene on the X chromosome, as the original studies on *Rhox5* had suggested (Lin *et al.* 1994, Maiti *et al.* 1996b, Sutton & Wilkinson 1997b), but instead rests in the middle of a large homeobox gene cluster (MacLean *et al.* 2005a; Fig. 1). The best-characterized *Rhox* gene cluster is in

mice, but *Rhox* gene clusters also exist at the syntenic position of the X chromosome in other mammals, including rats and humans (Lindsey & Wilkinson 1996b, Sutton *et al.* 1998, Geserick *et al.* 2002, Wayne *et al.* 2002a, MacLean *et al.* 2005a, Zhan *et al.* 2005, Morris *et al.* 2006). All the genes in this cluster were probably derived from a common ancestral homeobox gene that was duplicated multiple times by unequal crossing over (Jackson *et al.* 2006, MacLean *et al.* 2006, Morris *et al.* 2006, Wang & Zhang 2006, Geyer & Eddy 2008). Evidence suggests that this ancestral homeobox gene was also the precursor gene that gave rise to the single-copy *aristaless* homeobox gene in *D. melanogaster* (Maiti *et al.* 1996b, Sutton & Wilkinson 1997a, MacLean *et al.* 2005a). The common origin of the *Rhox* genes is strongly suggested by both their close physical proximity and the fact that all *Rhox* genes have two introns at positions within the homeobox region that are unique to this subfamily of homeobox genes (MacLean *et al.* 2005a, 2006). In addition, *Rhox* genes encode homeodomains more similar to each other than those encoded by other homeobox genes (Maiti *et al.* 1996b, MacLean *et al.* 2005a). Finally, some *Rhox* genes encode related motifs in the amino-terminal region (MacLean *et al.* 2005a, 2006, Jackson *et al.* 2006).

The *Rhox* gene cluster

The mouse *Rhox* gene cluster contains three subclusters: α , β , and γ (Fig. 1). The α subcluster was originally defined as having four genes (MacLean *et al.* 2005a), but following the refinement of the X chromosome genomic map and sequence analysis, four groups simultaneously reported multiple tandem duplications of three of the α subcluster genes, *Rhox2*, *Rhox3*, and *Rhox4*, making a total of 24 genes in the α subcluster (Jackson *et al.* 2006, MacLean *et al.* 2006, Morris *et al.* 2006, Wang & Zhang 2006). The duplicated copies (paralogs) of each of these three genes are almost identical in sequence (~95–100%). While it is not clear what selective forces are responsible for the recent amplification of these three genes in mice, it is clear that most of these paralogs are expressed and all but one (*Rhox3d*) encode full-length proteins and thus are presumably functional (Jackson *et al.* 2006, MacLean *et al.* 2006, Morris *et al.* 2006, Wang & Zhang 2006). The β subcluster has five genes, including the founding *Rhox* family member – *Rhox5* – and three other genes that had previously been given other names: *Rhox6* (*Psx1*), *Rhox8* (*Tox*), and *Rhox9* (*Psx2* and *Gpbx*) (Chun *et al.* 1999, Takasaki *et al.* 2000, Kang *et al.* 2004). The γ subcluster was originally defined as having three genes (MacLean *et al.* 2005a), but recently, a fourth member has been identified: *Rhox13* (Geyer & Eddy 2008). In total, 33 homeobox genes have so far been identified in the mouse *Rhox* gene cluster.

The *Rhox* gene cluster is rapidly evolving. One dramatic demonstration of this came from the discovery

that the rat *RHOX* gene cluster is smaller than its mouse counterpart (Fig. 1), primarily because it has only single copies of the α subcluster paralogs that in mice each have seven to eight copies (MacLean *et al.* 2005a, 2006, Jackson *et al.* 2006, Morris *et al.* 2006). This, coupled with the nearly identical sequence of the members of each paralog family, indicates that the expansion of the α subcluster paralogs occurred very recently, after the split of mice and rats in the rodent lineage. Also, unlike the mouse *Rhox* gene cluster, which contains two similar genes in the β subcluster (*Rhox6* and *Rhox9*), the rat *Rhox* gene cluster contains only one (MacLean *et al.* 2005a, 2006, Morris *et al.* 2006). The order of the genes in the mouse and rat *Rhox* gene clusters also appears to differ to some extent (Waterston *et al.* 2002 (build 37.1), Gibbs *et al.* 2004 (RGSC v3.4)), indicating the likelihood of gene rearrangements since the mouse/rat split (Fig. 1). However, this remains uncertain because the precise organization of both mouse and rat clusters has not yet been fully refined.

The human *RHOX* gene cluster is even smaller than the rat *Rhox* cluster. Only two human *RHOX* genes have been characterized at the syntenic portion of the X chromosomes (Geserick *et al.* 2002, Wayne *et al.* 2002a). One of them is *RHOXF1* (originally called *OTEX* and *hPEPP1*), which is androgen regulated and selectively expressed in human testes and thus is likely to have a role in spermatogenesis (Geserick *et al.* 2002, Wayne *et al.* 2002a). The other human *RHOX* gene is *RHOXF2A* (originally called *hPEPP2*), which, like *RHOXF1*, is selectively expressed in the testis (Geserick *et al.* 2002, Wayne *et al.* 2002a). Interestingly, *RHOXF2A* encodes a protein that has been shown to interact with both itself and a wide variety of other proteins, including nuclear transcription factors and cytoplasmic RNA decay-promoting proteins (Lehner & Sanderson 2004, Lim *et al.* 2006, Prasad *et al.* 2009). *RHOXF2A* has been classified as a member of the growing ‘cancer/testes’ gene family, a large group of genes that are not necessarily similar in sequence, but instead share the characteristic of being selectively expressed in the testis and a wide variety of tumors (Hofmann *et al.* 2008). Both human *RHOXF1* and *RHOXF2A* are capable of regulating *Rhox5* gene targets in mouse Sertoli cells (Hu *et al.* 2010), but it is not known what human genes they might regulate. At least one other *RHOX* gene exists in the human *RHOX* cluster – *RHOXF2B* – but neither it nor exonic remnants of other *RHOX* genes in the *RHOX* gene cluster have been characterized in terms of expression or function (Lander *et al.* 2001 (build 37.1)).

The rapid evolution of the *Rhox* gene cluster makes it a good candidate to have a role in speciation, a process that evidence suggests is largely driven by rapidly evolving X-linked genes (Turner & Hoekstra 2008). In addition to alterations in gene number and gene cluster organization in different species, rapid alterations in the

sequence of individual *Rhox* genes over evolutionary time may have contributed to speciation. As described earlier, the founding member of the *Rhox* family, *Rhox5*, has probably been subject to strong positive selection to undergo amino acid changing alterations (Sutton & Wilkinson 1997a); it remains to be determined whether the same is true for other *Rhox* family members. It would not be surprising if this was the case, as positive selection for changes in amino acid identity is common in large gene families, particularly those involved in reproduction (Chakrabarty *et al.* 2006, Soares *et al.* 2007, Rawn & Cross 2008). A definitive assessment of *RHOX* gene cluster evolution will require complete analysis and annotation of X chromosomes from a full set of mammals. At this point in time, even the mouse X chromosome remains to be fully analyzed; for example, a portion of the mouse *Rhox* cluster (between *Rhox2g* and *Rhox5*) has neither been cloned nor sequenced (as determined by manually evaluating BAC sequences available from NCBI and Ensembl).

Expression and functional role of *Rhox* cluster genes

All *Rhox* genes are selectively expressed in reproductive organs, and thus it is probable that they regulate events involved in reproduction (MacLean & Wilkinson 2005, MacLean *et al.* 2005b, Morris *et al.* 2006). In the mouse, analysis of a panel of 18 adult tissues demonstrated that all *Rhox* genes are selectively expressed in the ovary, testis, epididymis, and placenta (MacLean *et al.* 2005a; Fig. 2). Only *Rhox4*, *Rhox7*, and *Rhox8* were also expressed in non-reproductive organs; in thymus, stomach, and intestine respectively. Within the placenta, *Rhox4* is expressed in the chorionic trophoblast cells in the labyrinth and spongiotrophoblast layers of the placenta, suggesting that it may serve several different functions in this tissue (Jackson *et al.* 2003). The selective expression pattern of *Rhox* genes in reproductive organs is conserved, as the rat *Rhox* genes are also selectively expressed in the ovary, testis, epididymis, and placenta (Lindsey & Wilkinson 1996b, Maiti *et al.* 1996a, MacLean *et al.* 2005b, Morris *et al.* 2006; JA MacLean, unpublished observations), and the two best-characterized human *RHOX* genes appear to be specifically expressed in the human testis (Geserick *et al.* 2002, Wayne *et al.* 2002a). While *Rhox* genes normally exhibit highly specific and regulated expression patterns, some *Rhox* family members are ubiquitously expressed in tumors, including mouse *Rhox5*, *Rhox6*, and *Rhox9*, as well as human *RHOXF1* (Wilkinson *et al.* 1990, Rao *et al.* 2002a, Wayne *et al.* 2002a, Li *et al.* 2009).

Little is known about which cell types in adult reproductive organs express individual *Rhox* genes. Most progress on this front has been conducted on *Rhox5*, which, as described earlier, is expressed in mural granulosa cells in the ovary, principal cells in the caput epididymis, and Sertoli cells in the testis (Lindsey &

Wilkinson 1996b, 1996c, Pitman *et al.* 1998, Sutton *et al.* 1998, Rao *et al.* 2002b). Many other *Rhox* genes may be expressed in Sertoli cells, based on their expression in an enriched mouse Sertoli cell fraction (MacLean *et al.* 2005a), but confirmation by immunohistochemistry has not been done on most *RHOX* proteins. *Rhox4* is expressed in enriched adult interstitial cell fraction, suggesting that *Rhox4* is expressed in Leydig cells (MacLean *et al.* 2005a), but this also requires confirmation by immunohistochemistry. Recently, a careful analysis performed by Geyer & Eddy (2008) has demonstrated that *Rhox13* mRNA and *RHOX13* protein are expressed in differentiating spermatogonia and preleptotene spermatocytes, indicating that *Rhox13* is a good candidate to regulate early germ cell differentiation events and/or the transition from mitosis to meiosis. *Rhox3* and *Rhox11* are expressed in male germ cells at later stages of germ cell development than *Rhox13* (A Bettgowda & MF Wilkinson, unpublished observations), indicating that these two *Rhox* genes are candidates to regulate post-meiotic events in germ cells. Interestingly, Mueller *et al.* (2008) recently demonstrated that the mouse X chromosome is enriched for multi-copy genes that are expressed in post-meiotic male germ cells, suggesting that the *Rhox* cluster may be part of a large contingent of X-linked genes devoted to functions in the late stages of spermatogenesis.

While the cell types that express *Rhox* genes in adult reproductive organs are only beginning to be explored, a recent study conducted by Daggag *et al.* (2008) has given us a detailed view of the expression of *Rhox* genes in specific cell types within mouse embryonic gonads. Their study, which used both whole mount *in situ* hybridization and qPCR analyses, demonstrated that most *Rhox* genes are expressed in mouse embryonic gonads (Fig. 2). All but one of the *Rhox* genes are expressed in PGCs; the one exception, *Rhox8*, was expressed in the somatic cells neighboring the PGCs. Their study not only confirmed previous reports that *Rhox5* and *Rhox9* are expressed in PGCs (Pitman *et al.* 1998, Takasaki *et al.* 2001), but it also greatly extended the number of genes involved, particularly since they showed that PGCs express the *Rhox2* and *Rhox4* paralogs, which together consist of 15 genes. Interestingly, a recent report has found that *Rhox8* is dramatically upregulated in embryonic gonads from mice that have undergone sex reversal in response to loss of the 'pro-female' transcription factor FOXL2 (Uhlenhaut *et al.* 2009). This suggests that *Rhox8* might be part of the male-promoting program that converts the 'indifferent' early gonad into a male gonad. While most of the *Rhox* genes are expressed in both male and female PGCs, Daggag *et al.* found that three exhibit sex-specific expression. *Rhox10* is specifically expressed in male PGCs, while *Rhox6* and *Rhox9*, which are highly related in sequence, are expressed predominantly in female PGCs. Not only did some *Rhox* genes exhibit

sex-specific expression, but many of them also exhibited regulated temporal expression in PGCs during gonad development. Together, these data indicate that *Rhox* genes are good candidates to have roles in developmentally regulated and sex-specific events that occur in embryonic gonads.

In postnatal and adult mice, the expression patterns of the individual genes in the *Rhox* cluster are quite complex; many exhibit tissue-specific and developmentally regulated gene expression in both male and female reproductive tissues (Lindsey & Wilkinson 1996c, Pitman *et al.* 1998, MacLean *et al.* 2005a, 2005b). Their expression patterns suggest that *Rhox* genes may have both specific and broad roles regulating gametogenesis in both females and males. To date, the *in vivo* roles of only *Rhox5* and *Rhox9* (Pitman *et al.* 1998, Takasaki *et al.* 2000) have been reported (Fig. 2). As described earlier, *Rhox5*-null males have increased germ cell apoptosis and sperm motility defects, and they are subfertile (MacLean *et al.* 2005a). By contrast, *Rhox9*-null mice were not found to have any observable defects (Takasaki *et al.* 2001). One explanation is that the functions of *Rhox9* are compensated for by *Rhox6*, as these two genes are highly similar in sequence and expression pattern (Chun *et al.* 1999, Takasaki *et al.* 2000). But if *Rhox6* does compensate for *Rhox9*, it does so without being upregulated, as *Rhox6* mRNA is not increased in level in trophoblast cells, the testis, or ovary of *Rhox9*-null mice (Takasaki *et al.* 2001).

Most of the other genes in the mouse *Rhox* gene cluster have both unique and overlapping developmental expression patterns, so it is reasonable to suppose that they possess both unique and partially redundant functions (MacLean *et al.* 2005a). Circumstantial evidence supporting the notion that many RHOX transcription factors have distinct biological functions is that most possess homeodomains differing in amino acid residues at one or more of the four positions in the third helix known to make base-specific contacts with DNA (MacLean *et al.* 2005a). For example, RHOX5, RHOX6, RHOX9, and RHOX12, all of which are co-expressed in the placenta, have different amino acids at two or more of these four positions. Thus, it seems likely that these four RHOX transcription factors regulate, at least in part, distinct downstream targets (of note, however, is that the two different 'DNA-recognition' amino acids in RHOX6 and RHOX9 are conservative/similar substitutions). To ultimately discern the unique and redundant roles of the *Rhox* cluster genes, it will probably require a combination of approaches that inactivate/deplete individual *Rhox* genes, combinations of *Rhox* genes, and even the entire *Rhox* gene cluster.

In vitro studies will no doubt also contribute to our understanding of the biological roles of *Rhox* cluster genes (Fig. 2). In this regard, Jackson *et al.* (2002) showed that *Rhox4b* (*Ehox*) is expressed in ES cells and that

antisense *Rhox4b* RNA inhibited ES cell differentiation *in vitro*. Conversely, ES cell differentiation was promoted in response to *Rhox4b* overexpression. These experiments, along with assays to measure self-renewal capacity, provided evidence that *Rhox4b* has two functions in ES cells: it promotes their differentiation and inhibits their self-renewal. It will be interesting to determine whether other *Rhox4* paralogs share this property, as the antisense RNA used by Jackson *et al.* probably targeted all of the other six *Rhox4* gene paralogs. A role for *Rhox4* genes in early development is consistent with *in situ* hybridization analyses showing that *Rhox4* transcripts exhibit a developmentally regulated pattern of expression in the early embryo; they are initially restricted to extraembryonic endoderm (in e6.5 embryos), and later (e8.5–10.5) they are expressed in the embryo proper, first in the anterior foregut endoderm and then in the pharyngeal pouches (Jackson *et al.* 2003).

Regulation of *Rhox* cluster transcription

The field is only just beginning to explore the mechanisms that regulate most of the members of the *Rhox* gene cluster. One notable exception is the founding member, *Rhox5*, whose regulation has been examined in detail, as described earlier in this review. Here, we summarize what is known about the regulation of other *Rhox* genes, including two studies that have uncovered putative global regulatory mechanisms controlling several genes in the *Rhox* gene cluster.

To ensure proper development, the well-known *Hox* homeobox gene clusters have evolved specialized regulatory mechanisms to control the time and place that the transcription factors encoded by the genes within these clusters are expressed. Perhaps the most striking discovery that has been made regarding *Hox* gene clusters is that they exhibit a co-linear pattern of expression, such that their physical order on a chromosome correlates with their expression pattern. In particular, the timing, position, and level of expression of individual *Hox* genes during embryonic development follow their position within a given *Hox* gene cluster (Spitz *et al.* 2003). Similarly, MacLean *et al.* (2005a) found that testis-expressed *Rhox* genes exhibit a temporal and quantitative co-linear expression pattern in which the order of these genes within each subcluster on the X chromosome correlates with their timing and relative strength of expression during postnatal testes development. It will be interesting to determine the functional relevance of this co-linear expression pattern, as well as the underlying mechanism responsible for it. With regard to the latter, one could envisage it being directed by global transcriptional enhancer elements. By analogy, a global enhancer has been identified in the *Hoxd* cluster that drives the co-linear expression

pattern of its genes during embryonic development (Spitz *et al.* 2003).

A different line of evidence for a global *Rho*x cluster-regulatory mechanism was obtained by Oda *et al.* (2006). As described earlier, these authors demonstrated that *Rho*x5 is selectively expressed in extra-embryonic tissues, not the embryo proper, as a result of DNA methylation blocking *Rho*x5 expression in the latter. Extending their analysis to other *Rho*x genes, they found that, like the *Rho*x5 *Pp*, the promoter regions of the *Rho*x2, *Rho*x6, and *Rho*x9 genes switch from a hypomethylated state in eight-cell embryos and blastocysts to a hypermethylated state in mid-gestation (e8.5–e9.5) embryos. They found that methylation of these promoters occurs selectively in the embryo proper, not extra-embryonic tissue (trophoblasts and yolk sac), consistent with a repression mechanism specifically preventing the expression of *Rho*x genes in the embryo proper. Causal evidence that this is indeed the case was the authors' finding that mouse embryos lacking both *de novo* DNMTs – DNMT3a and DNMT3b – had greatly elevated expression of most *Rho*x genes. In contrast, most other genes on the X chromosome – including the *Rho*x-related *Esx1* gene, which is far distant from the *Rho*x gene cluster – were not upregulated in the double-mutant embryos. Repression was mediated specifically in the embryo proper, as trophoblasts from double-mutant embryos did not exhibit significantly upregulated *Rho*x cluster gene expression. This was consistent with the fact that *Rho*x gene cluster promoters are normally already hypomethylated in extra-embryonic tissues (Schutt *et al.* 2003, Oda *et al.* 2006).

DNMTs can regulate transcription either directly or indirectly. Oda *et al.* addressed which might be the case for *Rho*x cluster genes by comparing the methylation status of their promoters in double-mutant embryos versus control mouse embryos. They found that all the *Rho*x gene promoters that they tested were less methylated in double-mutant embryos than control embryos, providing evidence that DNA methylation directly regulates their transcription. Methylation of the *Rho*x6 and *Rho*x9 promoters required both DNMT3b and DNMT1, but not DNMT3a, based on analysis of single-mutant mice for these three factors. Likewise, the transcriptional repression of *Rho*x6 and *Rho*x9 required DNMT3b, not DNMT3a (DNMT1 was not tested). In contrast, *Rho*x2 promoter methylation could be mediated by either DNMT3a or DNMT3b, as only double-mutant (*Dnmt3a*^{−/−} *Dnmt3b*^{−/−}) embryos, not compound heterozygous (e.g. *Dnmt3a*^{−/+} *Dnmt3b*^{−/−}) mouse embryos, had a hypomethylated *Rho*x2 promoter. Together, these data supported the notion that the *Rho*x gene cluster is controlled by a global DNA methylation-mediated mechanism that confines the expression of most *Rho*x genes to extra-embryonic tissues in mid-gestation embryos.

Oda *et al.* obtained evidence that this global regulatory mechanism regulates not only the *Rho*x gene cluster, but also a short region upstream and a ~0.3 Mb region downstream, which together with the *Rho*x gene cluster form a domain on the X chromosome that is ≥1 Mb in length. The evidence that this 'methylation-targeted domain' extends a short region upstream of the *Rho*x gene cluster came from their identification of a gene just ~2 kb upstream of *Rho*x1, called *Gm9*, whose promoter region was demethylated in double-mutant mouse embryos lacking DNMT3a and DNMT3b. Accompanying this demethylation event was the ectopic expression of *Gm9* in double-mutant embryos. In contrast, the genes upstream of *Gm9* (including one <20 kb upstream) did not exhibit altered methylation or expression, implying that the upstream boundary of the methylation-targeted domain is just upstream of *Gm9*. The evidence that the methylation-targeted domain extends downstream of the *Rho*x gene cluster was the finding that two CpG island-containing gene promoters downstream of the *Rho*x gene cluster become demethylated in double-knockout mice embryos. However, there is doubt as to the relevance of this demethylation event, as their respective genes did not appear to be expressed at higher levels in double-knockout mice than in control mice. Furthermore, a *Rho*x gene at the 3' end of the *Rho*x cluster, *Rho*x12, did not exhibit upregulated expression in double-knockout embryos. Given that *Rho*x12 is in the γ subcluster, this suggests the possibility that the downstream boundary of the methylation-targeted domain is between the β and γ subclusters. This predicts that all the genes in the α and β subclusters should be upregulated in double-knockout mice. Indeed, all the α and β subclusters that were tested (*Rho*x1, *Rho*x2, *Rho*x3, *Rho*x4, *Rho*x5, *Rho*x6, and *Rho*x9) exhibited this regulation. In conclusion, the available evidence from Oda *et al.* suggests the existence of a methylation-targeted domain in the X chromosome that is comprised of the 5' end of the *Rho*x gene cluster (the α and β subclusters) and a short region upstream. Whether this domain also includes the 3' end of the *Rho*x cluster (the γ subcluster) and genes downstream of that remains to be definitively determined.

The role of DNA methylation in regulating *Rho*x gene cluster transcription has also been studied in cultured cell lines. Li *et al.* (2009) demonstrated that the mouse *Rho*x5, *Rho*x6, and *Rho*x9 genes are induced by the DNA methylation inhibitor 5AzaC in mouse cell lines, implying that several *Rho*x genes are repressed in cell lines by DNA methylation. Likewise, they showed that two best-characterized human *RHOX* genes, *RHOXF1* and *RHOXF2B*, are induced by 5AzaC in human cell lines. Further evidence that *Rho*x genes are repressed by DNA methylation was obtained by Oda *et al.* (2006) who found that the *Rho*x2, *Rho*x5, *Rho*x6, and *Rho*x9 gene promoters are hypermethylated in ES cells. Analysis of ES cells lacking different combinations of DNMTs

demonstrated that the methylation of these *Rhox* promoters can be mediated by either DNMT3a or DNMT3b. In contrast, the requirement for DNMT1 depended on the *Rhox* gene promoter tested; *Rhox6* and *Rhox9* promoter methylation was dramatically inhibited in *Dnmt1*-mutant ES cells, whereas *Rhox2* and *Rhox5* promoter methylation was little affected. While these findings suggest that *Rhox* genes are transcriptionally repressed by DNA methylation in ES cells, this was not directly tested, as the authors did not examine the expression levels of *Rhox* genes in control and *Dnmt*-mutant ES cells. However, it seems likely to be the case, as a recent study has demonstrated that a surprisingly large number of X-linked genes, including *Rhox2*, are upregulated in DNMT-deficient ES cells (Fouse *et al.* 2008). Given the utility of using cell lines for in-depth molecular studies, it will be important to continue conducting *in vitro* studies in combination with *in vivo* studies to obtain an 'integrated view' of *Rhox* cluster gene regulation.

The only *Rhox* gene promoter that has been studied in depth besides *Rhox5*'s alternative promoters is the *Rhox4b* (*Ehox*) promoter (Lee *et al.* 2006). Lee *et al.* (2006) found that the *Rhox4b* promoter contains a critical CCAAT box within the first ~100 bp of 5' flanking sequence that is necessary for *Rhox4b* transcription (as defined by a transfected reporter) and binds to the transcription factor NFY. Downstream of this NFY-binding element is an SP1 transcription factor family consensus-binding site that is necessary for maximal *Rhox4b* promoter activity. This is of interest given that SP1 family members have been shown to bind and regulate the expression of the *Rhox5Pd* in primary granulosa cells and cell lines (Rao *et al.* 2002a, MacLean *et al.* 2005b). Furthermore, preliminary characterization of the *Rhox8* promoter has also identified a key SP1 consensus site required for *Rhox8* transcription (J A MacLean, unpublished observations). Thus, regulation by SP1 family members may be a common feature of *Rhox* genes. Like most *Rhox* cluster genes, *Rhox4b* is expressed in ES cells and the placenta, but it also has the unique property of being expressed in the thymus (Jackson *et al.* 2002, 2003). It will be interesting to determine what peculiar aspects of the *Rhox4b* promoter allow it to be expressed in the thymus. Given the wealth of knowledge in the field of immunology (and T cells in particular), it may be instructive to learn about genes regulated by *Rhox4b* in the thymus as a means to gain insight into *Rhox4b*'s function in embryonic development and the placenta. *Rhox4b* is one of the seven gene paralogs almost identical in sequence; most encode identical homeodomain regions, and the entire deduced amino acid sequence of RHOX4B only differs from that of RHOX4F and RHOX4G by two amino acids (MacLean *et al.* 2006). It will be interesting to know whether all seven *Rhox4* paralogs are regulated in an identical manner and what selection pressures might cause them to undergo divergent regulation over future evolutionary time.

***Rhox* cluster-derived genes outside of the *Rhox* cluster**

As described above, the *Rhox* gene cluster has undergone several relatively recent alterations, including its expansion in rodents, particularly in mice, which have tandem duplications of most of the α subcluster genes. Conversely, ancient events have probably reduced the size of the *Rhox* gene cluster. In particular, two genes were almost certainly relocated from the *Rhox* gene cluster to distant sites on the X chromosome as a result of ancient chromosomal inversion events (Svingen & Koopman 2007). These two 'vagabond genes' are *Esx1* (also called *Spx1* in mice; *ESX1* in humans) and *Arx* (ARX in humans; Fig. 1). The evidence for their close relationship with the *Rhox* gene family is threefold. First, the *Esx1* and *Arx* genes are both on the X chromosome, like the *Rhox* cluster. Second, the *ESX1* and *ARX* homeodomains are similar in sequence to homeodomains in RHOX family members. Third, both the *Esx1* and *Arx* genes have the hallmark exon-intron structure specifically characteristic of *Rhox* genes (i.e. introns located at two particular sites within the homeodomain-encoding region).

Esx1/ESX1

Esx1 is selectively expressed in testes and placenta in both humans and mice (Branford *et al.* 1997, Li & Behringer 1998, Fohn & Behringer 2001, Yeh *et al.* 2005). In the mouse testis, *in situ* hybridization analyses indicated that *Esx1* transcripts are specifically expressed in spermatogonia, spermatocytes, and round spermatids in stages IV–VII of the seminiferous epithelial cycle (Branford *et al.* 1997). Although *Esx1* transcripts are first detectable in pre-meiotic germ cells, *ESX1* protein is only detectable in post-meiotic round spermatids, suggesting that *ESX1* is subject to translation control (Yeh *et al.* 2005). However, despite its expression in round spermatids, *ESX1* does not appear to have a non-redundant role in spermatogenesis, as *Esx1*-null male mice are fertile and do not exhibit obvious testicular defects (Li & Behringer 1998). Instead, these mice exhibit defective placental development involving the maternal–fetal interface, leading to reduced embryo size and increased placental size. Also consistent with a placental-specific defect, *Esx1*-null mice are ~20% smaller than normal at birth, but later reach normal size. The growth defect was only observed when the mutant *Esx1* gene was inherited from the mother, consistent with the maternal-specific (i.e. imprinted) expression of mouse X-chromosomal genes in placenta. The growth-promoting ability of *Esx1* during embryonic development contrasts with its ability to inhibit the growth of tumor cells. One study showed that a naturally produced C-terminal *ESX1* fragment inhibits the degradation of cyclins and thereby causes cell cycle

arrest (Ozawa *et al.* 2004), while another study showed that ESX1 slows tumor growth by homeodomain-dependent inhibition of *Kras* transcription and amino-terminal domain-dependent reduction in tumorigenicity (Nakajima *et al.* 2008). Another intriguing aspect of *Esx1* is that, like *Rhox5*, it has undergone rapid evolution in mammals (Wang & Zhang 2007). Evidence suggests that positive selection for rapid changes has primarily occurred in the C-terminal region, which is the region that regulates cyclin degradation and cell division. It will be interesting to discover the selective forces that might be responsible for this, and what consequences this has on ESX1's role in reproduction.

Arx/ARX

The *Arx* gene exhibits a different expression pattern than *Esx1*. *Arx* is specifically in developing male gonads as well as several regions of the developing and adult brain (Kitamura *et al.* 2002, Gecz *et al.* 2006). Most studies on *Arx* have focused on its role in the brain, as it is commonly mutated in mental retardation patients, and studies in *Arx*-mutant mice have shown that ARX is crucial for development of the forebrain (Kitamura *et al.* 2002, Gecz *et al.* 2006). Indeed, because of the dramatic brain defects that result from its loss, *Arx*-null mice typically undergo epileptic seizures and perinatal death, precluding analysis of ARX's role in fertility (Kitamura *et al.* 2002, Marsh *et al.* 2009). However, this has not prevented an analysis of the role of ARX in the developing male gonad in embryos. Analysis of *Arx*-mutant male embryos revealed that their testes had a dysplastic interstitium accompanied by reduced expression of a Leydig cell marker, which together suggested that these mice had a defect in fetal Leydig cell differentiation (Kitamura *et al.* 2002). This defect in Leydig cells is probably not a primary event, as ARX protein is barely detectable in Leydig cells; instead, it is expressed at high levels in fibroblast-like cells adjacent to the Leydig cells in the interstitium. A role for ARX in Leydig cell function is likely to be conserved, as some humans with mutations in the *ARX* gene have reduced numbers of Leydig cells and reduced testosterone levels (Ogata *et al.* 2000). It will be important in the future to clarify the role of ARX in fetal Leydig cell function, including their ability to produce androgens.

Perspective

The discovery of the *Rhox* gene cluster has opened up a new frontier in reproductive biology. The 33 homeobox genes in this cluster are selectively expressed in the male and female reproductive tract, suggesting that *Rhox* genes probably encode transcription factors devoted to regulating and promoting male and female fertility. In the future, it will be intriguing to dissect the redundant and non-redundant functions of the *Rhox* genes in mice.

To understand the molecular networks that drive these biological functions, the direct gene targets of RHOX transcription factors in different reproductive cell types will need to be identified. Some progress has already been made on this front with regard to androgen/AR-regulated gene networks in somatic cells (i.e. via the androgen/AR-regulated *Rhox5* gene), but it will be important to also identify the *Rhox* gene-regulated networks in developing germ cells. While the study of *Rhox* gene function in mice has the potential to illuminate the role of *Rhox* genes in human fertility, there is clearly also a need to directly study the expression and function of human *RHOX* genes. For example, it will be crucial to assess the function of *RHOX* genes in human ES cells, including how their development into gametes is regulated by *RHOX* genes. There is also a need to obtain a deeper understanding of how *Rhox* genes are transcriptionally regulated. *Rhox* genes are one of the few genes whose cell type-specific expression has been shown to be regulated by DNA methylation. This makes them a model system to elucidate the underpinnings and physiological importance of this key 'epigenetic' regulatory mechanism. Finally, the unusual evolution of the *Rhox* gene cluster and its individual family members is worth studying in more depth, particularly since the rapid evolution of *Rhox* genes may have contributed to speciation and the development of different reproductive strategies in different organisms.

Declaration of interest

The authors declare that there is no conflict of interest that could be perceived as prejudicing the impartiality of the research reported.

Funding

The authors are funded by the National Institute of Health, grants HD45595, HD53808, and HD55268, which supported work on the *Rhox* gene cluster.

Acknowledgements

The authors would like to thank Dr JoAnne Richards (Baylor College of Medicine) and fellows from the Wilkinson laboratory (Marcy Beildeck, Madhuvanthi Ramaiah, Anilkumar Bettgowda, and Hye-Won Song) for their helpful comments during the preparation of this review.
