Abstract

Although the mRNA that encodes progesterone receptor membrane component 1 (PGRMC1) is present in mammalian oocytes, nothing is known about either PGRMC1's expression pattern or function in oocytes during maturation, fertilization, and subsequent embryonic development. As PGRMC1 associates with the mitotic spindle in somatic cells, we hypothesized that PGRMC1 is involved in oocyte maturation (meiosis). Western blot analysis confirmed the presence of PGRMC1 in bovine oocytes. This study also shows that PGRMC1 is present at the germinal vesicle (GV)- and MII-stage oocytes and is associated with male and female pronucleus formation of the zygote and is highly expressed in blastocysts. A more detailed examination of PGRMC1 localization using confocal imaging demonstrated that in GV-stage oocytes, PGRMC1 was concentrated throughout the GV but did not localize to the chromatin. With the resumption of meiosis *in vitro*, PGRMC1 concentrated in the centromeric region of metaphase I chromosomes, while in the anaphase I/telophase I stages the majority of PGRMC1 concentrated between the separating chromosomes. At the metaphase II stage, PGRMC1 re-associated with the centromeric region of the chromosomes. A colocalization study demonstrated that PGRMC1 associated with the phosphorylated form of aurora kinase B, which localizes to the centromeres at metaphase. Finally, PGRMC1 antibody injection significantly lowered the percentage of oocytes that matured and reached the metaphase II stage after 24 h of culture. The majority of the PGRMC1 antibody-injected oocytes arrested in the prometaphase I stage of meiosis. Furthermore, in most of the PGRMC1 antibody-injected oocytes, the chromosomes were disorganized and scattered. Taken together, these data demonstrate that PGRMC1 is expressed in bovine oocytes and its localization changes at specific stages of oocyte maturation. These observations suggest an important role for PGRMC1 in oocyte maturation, which may be specifically related to the mechanism by which chromosomes segregate.

Reproduction (2010) **140** 663–672

Introduction

Progesterone receptor membrane component 1 (PGRMC1) is an evolutionary conserved protein, which is involved in regulating numerous biological functions (Cahill 2007). Recently, PGRMC1 was detected among the proteins of the mitotic spindle (Nousiainen *et al.* 2006), suggesting a role for it in mitosis. Interestingly, PGRMC1 is also expressed in bovine (Dode *et al.* 2006), rat (Peluso *et al.* 2006), and human oocytes (Wood *et al.* 2007). Moreover, the mRNA that encodes PGRMC1 is present in bovine oocytes at a very high level similar to that of actin (Dode *et al.* 2006). In spite of its high level of expression, little is known about PGRMC1 and oocyte function. Since PGRMC1 is present in mitotic spindle

(Nousiainen *et al.* 2006), it could be directly involved in regulating oocyte maturation (meiosis).

In mammalian ovaries, oocytes are arrested in prophase of the first meiotic division (i.e. germinal vesicle (GV) stage) until the gonadotropin surge induces meiosis in oocytes of preovulatory follicles. Nuclear meiotic maturation of oocytes includes condensation of chromosomes and the sequential progression through prometaphase I, metaphase I, anaphase I, and telophase I. The meiotic progression then arrests at metaphase II (Eppig *et al.* 2004). This sequence of meiotic events also occurs *in vitro*. For example in cows, fully grown oocytes extracted from follicles larger than 2 mm are capable of resuming meiosis *in vitro* with ~90% of the oocytes reaching metaphase II (Sirard *et al.* 1988). Regardless of

whether meiosis occurs *in vivo* or *in vitro*, this process requires the precise coordination between the chromosomes and the tubulin-based meiotic spindle.

To guarantee the coordinated interaction between the chromosomes and the meiotic spindle, the activity and localization of various spindle-associated proteins is strictly regulated (Musacchio & Salmon 2007). One important spindle-associated protein is aurora kinase B (AURKB). AURKB is a protein kinase that is a component of the chromosomal passenger complex (CPC), which also consists of an inner centromere protein, INCENP, which binds AURKB (Ruchaud *et al.* 2007). During mitosis, AURKB plays a critical role in chromosome–microtubule interactions (Hauf *et al.* 2003). This kinase is localized to the kinetochores from prophase to metaphase and relocates to the central spindle and the midbody in cytokinesis (Carmena & Earnshaw 2003). The altered expression AURKB is implicated in defects of centrosome function, spindle assembly, and chromosomal instability (Ota *et al.* 2002, Fu *et al.* 2007).

AURKB is also expressed in mammalian oocytes (Jelinkova & Kubelka 2006, Swain *et al.* 2008, Uzbekova *et al.* 2008, Shuda *et al.* 2009). It gradually becomes phosphorylated on threonine 232 (Thr232) during oocyte maturation. Phosphorylation of AURKB activates this kinase and leads to the phosphorylation of histone H3 and the gradual condensation of chromatin (Jelinkova & Kubelka 2006, Wang *et al.* 2006, Swain *et al.* 2008). Moreover, altered AURKB activity increases the risk in chromosome congression failure, nondysjunction, and aneuploidy in mammalian oocytes (Vogt *et al.* 2009).

Since PGRMC1 is highly expressed in bovine oocytes and zygotes (Dode *et al.* 2006) and it is localized to the mitotic spindle (Nousiainen *et al.* 2006), we hypothesized that PGRMC1 is involved in meiosis. This study was designed to determine the role of PGRMC1 in oocyte meiotic division by monitoring its i) localization during oocyte *in vitro* maturation, IVF, and early development; ii) relationship to changes in the activity of AURKB; and iii) function by injecting an antibody to PGRMC1 into oocyte before *in vitro* maturation.

Results

PGRMC1 expression in oocytes, zygotes, and embryos

As shown in Fig. 1, western blot analysis demonstrated that PGRMC1 was specifically detected in bovine oocytes as a ≈ 26 kDa protein. Having established that this antibody specifically detects bovine PGRMC1, it was utilized to localize PGRMC1 in bovine oocyte undergoing meiosis *in vitro*. Note that under culture conditions used in this study, GV-stage oocytes resume meiosis with 93% of the oocytes reaching metaphase II by 24 h of culture (Table 1). The rate of IVF and blastocyst development was respectively 89.5 and 37.3%. In a preliminary study, PGRMC1 was localized at the time

Figure 1 Detection of PGRMC1 in bovine oocytes. Western blot analysis showing PGRMC1 expression in bovine oocytes. A western blot using lysate prepared from bovine ovarian cortex, conducted in the absence of the PGRMC1 antibody, is shown as a negative control (–) while a western blot using this lysate conducted in the presence of the PGRMC1 antibody is shown as a positive control (+). Western blot using lysate prepared from bovine oocytes is shown in lane 3. Representative blots from three independent experiments are shown.

of collection or after *in vitro* maturation, IVF, and embryo culture, and then observed in epifluorescence microscopy. As shown in Fig. 2, PGRMC1 was present within GV in immature oocytes and associated with the MII plate of *in vitro* matured oocytes. After IVF, PGRMC1 was associated with the female and the male pronucleus. At the blastocyst stage, virtually all the blastomeres showed positive staining for PGRMC1.

Having confirmed that PGRMC1 was present in bovine oocytes and embryos, changes in the localization of PGRMC1 during oocyte maturation was examined in more detail using confocal microscopy. This analysis revealed that PGRMC1 associates with the metaphase II chromosomes at distinct focal points (Supplementary Movie 1, see section on supplementary data given at the end of this article), which suggests that PGRMC1 localizes to the centromere.

As shown in Fig. 2, PGRMC1 was not detectable in the ooplasm. In fact, the fluorescent staining of the

*Time in culture. Values in bold indicate the highest percentage of oocytes in specific stages of meiosis for each time in culture. Pro I, prophase I; Promet I, Prometaphase I; Met I, metaphase I; Ana I, anaphase I; Telo I, telophase I; Met II, metaphase II.

Figure 2 (A) A GV-stage negative control in which IgGs were used in place of the primary PGRMC1 antibody. PGRMC1 localization in prophase I (GV stage) (B), metaphase II oocyte (C, polar view and D, lateral view), pronuclear stage (E), and blastocyst-stage embryo (F). PGRMC1 (red) immunostaining is merged with DAPI (DNA; blue). Note that PGRMC1 appears to associate with germinal vesicle in immature oocyte and with the metaphase chromosomes in MII oocyte. In (C) and (D) the insets show the magnified metaphase II plate. In zygotes, PGRMC1 is associated with male and female pronucleus and is localized in the blastomeres up to the blastocyst stage of development. In (E) the insets show the magnified pronuclei; PGRMC1 and nuclear staining are shown separately to better illustrate pronuclear localization. Representative images in epifluorescence are shown. This immunocytochemical analysis was conducted on a total of 98 oocytes at the following stages: 39 in prophase I, 27 in metaphase II, 17 in pronuclear, and 15 in blastocyst.

cytoplasm in the IgG control was similar to that observed in the PGRMC1 antibody immunostained group (compare Fig. 2A and B).

PGRMC1 expression in oocytes during meiosis in vitro and PGRMC1 and AURKB colocalization

To test this assumption, PGRMC1 was colocalized with AURKB, which is known to associate with proteins that comprise the centromere at metaphase (Ruchaud *et al.* 2007). This study demonstrated that in prophase I (GV stage) oocytes, PGRMC1 and AURKB were highly expressed within the GV, but neither protein was associated with the chromatin. At prometaphase I (i.e. after GV breakdown), both proteins began to associate with the chromosomes and this association was more evident in metaphase I oocytes. During anaphase I/ telophase I stages, both proteins dissociated from the chromosomes and concentrated in the mid-zone and the midbody of the separating chromosomal plates. At anaphase I, these two proteins colocalized throughout the mid-zone. During telophase, some AURKB colocalized to PGRMC1 at the center of the midbody between the chromosomal plates. Interestingly, some AURKB at the periphery of the midbody was not colocalized with PGRMC1. PGRMC1 and AURKB appeared to localize to the spindle pole in some oocytes. However, this was not consistently observed and its functional significance, if any, remains to be determined in further studies. Finally, at the metaphase II stage, both PGRMC1 and AURKB again colocalized to the centromeric region of the chromosomes (Fig. 3).

In a third study, the relationship between the AURKB and the Thr232 phosphorylated (active) form of AURKB was assessed. This study illustrated that AURKB began to

associate with the chromatin in all of the prometaphase I oocytes, but the active form of AURKB was only barely detectable in about half of these oocytes. By metaphase I, staining for phosphorylated AURKB was readily detectable in all the oocytes and remained so up to the metaphase II stage (Fig. 4). Importantly, after GV breakdown, PGRMC1 was always concentrated to those subcellular compartments where the active, phosphorylated form of AURKB was present. This was particularly evident at the telophase I stage (compare Figs 3 and 4).

PGRMC1 and oocyte maturation

To begin to assess the role of PGRMC1 on oocyte maturation, GV-stage oocytes within their cumulus cell mass were injected with antibody to PGRMC1 while controls were injected with either IgG or PBS. After 24 h, only 22% ($n=68$) of the oocytes injected with the PGRMC1 antibody progressed to metaphase II compared with 74% ($n=39$; $P<0.05$) and 68% ($n=43$; $P<0.05$) of PBS or IgG-injected oocytes respectively (Fig. 5A). A high proportion of PGRMC1 antibody-injected oocytes (57.4%) arrested in prometaphase I stage. Some of the PGRMC1 antibody-injected oocytes progressed beyond prometaphase I as 5.8% ($n=4$), 8.8% ($n=6$), and 22% ($n=15$) reached metaphase I, anaphase/telophase I, and metaphase II respectively, with most of these possessed chromosomes that were disorganized and scattered throughout the ooplasm (compare Fig. 5C with B).

Discussion

This study confirms and expands a previous mRNA-based observation (Dode *et al.* 2006) by demonstrating that PGRMC1 is present in bovine oocytes as a

Figure 3 Colocalization of PGRMC1 and AURKB during bovine oocyte maturation. Representative confocal images showing PGRMC1 and AURKB localization at the indicated meiotic stages, from the prophase I (GV stage) to the metaphase II. Images were cropped to show the area containing the chromatin. PGRMC1 (red) and AURKB (green) immunostaining are merged with DAPI (DNA; blue) counterstained image to visualize the specific protein–chromosomes associations. In the right column, PGRMC1 and AURKB images are merged to reveal sites of their colocalization (orange). Note that the images of anaphase I and telophase I are in lateral view to better illustrate the relationship between PGRMC1 and AURKB at the mid-zone and the midbody. The images of metaphase I and metaphase II are shown in a polar view to better illustrate the relationship between PGRMC1, AURKB, and the chromosomes. This immunocytochemical analysis was conducted on a total of 199 oocytes at the following stages: 21 in prophase I, 17 in prometaphase I, 39 in metaphase I, 38 in anaphase I, 34 in telophase I, and 50 in metaphase II.

Figure 4 Colocalization of AURKB and phosphorylated AURKB during bovine oocyte maturation. Representative confocal images showing the relationship between AURKB and the active (phosphorylated) form of AURKB (pAURKB) from the prophase I (GV stage) to the metaphase II stages of meiosis. pAURKB (red) and AURKB (green) immunostaining are merged with DAPI (DNA; blue) counterstained image. In the right column, pAURKB and AURKB images are merged to reveal sites of their colocalization (orange). Images were cropped to show the area containing the chromatin. The insets in the prometaphase stage are images of pAURKB staining. This immunocytochemical analysis was conducted on a total of 239 oocytes (38 in prophase I, 18 in prometaphase I, 43 in metaphase I, 41 in anaphase I, 53 in telophase I, and 46 in metaphase II).

Figure 5 (A) Effect of PGRMC1 antibody injection on bovine oocyte maturation. *Indicates a value that is significantly different ($P < 0.05$) from either PBS or IgG. After 24 h of culture, oocytes were stained with propidium iodide (red) to reveal the chromosomes. (B) Shows chromosomes that are precisely arranged in a metaphase plate (i.e. control) while (C) shows a bovine oocyte 24 h after being injected with PGRMC1 antibody. Note that the chromosomes are not aligned and disorganized.

≈26 kDa protein. This is consistent with PGRMC1 western blots obtained from lysates of other organs and cell types such as porcine liver (Meyer *et al.* 1998); human and rat granulosa and luteal cells (Engmann *et al.* 2006, Peluso *et al.* 2006); mouse and human smooth muscle, uterus, and placenta (Zhang *et al.* 2008). This study also shows that PGRMC1 is present at the GV- and MII-stage oocytes and is associated with male and female pronucleus formation of the zygote and is highly expressed in blastocysts. Specifically, before fusion of the pronuclei, PGRMC1 localizes to several foci that appear to be within nucleolar precursor bodies (NPBs; Fulka & Fulka 2010). NPBs have been observed at the pronuclei of bovine zygotes and apparently function in nucleolus formation (Flechon & Kopečný 1998). Moreover, NPBs are the sites of rRNA synthesis with rRNA encoding polypeptides that comprise ribosomes and therefore are essential for the synthesis of proteins that ultimately direct embryonic development (Flechon 2006).

As fertilization and embryonic development are dependent on successful oocyte maturation, the present work focused more intensely on changes in PGRMC1 after the resumption of meiosis. This study, using confocal microscopy, reveals that PGRMC1 starts to concentrate on the chromatin. This becomes more evident at metaphase I, where PGRMC1 is restricted to the centromeric region of bivalent chromatids. During anaphase I and telophase I, PGRMC1 dissociates from the chromosomes and localizes in the mid-zone and midbody respectively. At metaphase II, PGRMC1 again concentrates at the centromeric region of the chromosomes. These temporal changes in the localization of PGRMC1 during oocyte maturation suggest an important role for PGRMC1 in the process that governs meiotic progression of the oocyte.

That PGRMC1 localizing to the chromosomes is important and is supported by the finding that PGRMC1 colocalizes with AURKB at specific stages of the oocyte meiotic progression. It is well known that AURKB is expressed during oocyte meiosis in cows (Uzbekova *et al.* 2008), mice (Swain *et al.* 2008, Shuda *et al.* 2009, Vogt *et al.* 2009), and pigs (Jelinkova & Kubelka 2006). In general, our observations on AURKB are in agreement with the known changes in the localization of AURKB, which occur during oocyte meiotic division. The one notable exception is the study by Uzbekova *et al.* (2008) who failed to detect AURKB within the GV, while this study did. The use of a different AURKB antibody and/or a different fixation protocol likely account for the differences observed in these two studies.

While the issue of AURKB within the GV remains to be resolved, it is important to appreciate that AURKB is a serine/threonine protein kinase, which regulates many processes during mitosis and meiosis (Kaitna *et al.* 2002, Shannon & Salmon 2002, Vogt *et al.* 2009). In meiosis, AURKB is involved in chiasma resolution and its activation (i.e. phosphorylation on Thr232) and is correlated with cytokinesis and first polar body formation (Kaitna *et al.* 2002, Vogt *et al.* 2009). In addition, treatment with a pharmacological inhibition of AURKB results in the failure to extrude the first polar body. Furthermore, in porcine oocytes, AURKB activity increases after prometaphase I reaching a maximum at metaphase I and thereafter is maintained until metaphase II (Jelinkova & Kubelka 2006). This study is consistent with these observations and further reveals that during telophase I AURKB localizes within the spindle midbody. Interestingly, not all of the AURKB within the spindle midbody is active. Rather only the AURKB at the center of the midbody is active (phosphorylated). Interestingly, the active fraction of AURKB appears to colocalize with PGRMC1. This implies that both PGRMC1 and AURKB are involved in the mechanism by which asymmetric cytokinesis occurs during first polar body formation.

The fact that PGRMC1 only appears to colocalize with active AURKB raises the issue of whether PGRMC1 is essential for the activation of AURKB. Recently, a fluorescence resonance energy transfer-based assay was used to assess phospho-Thr²³² AURKB activity in anaphase HeLa cells. Similar to our observations in the bovine oocyte, this study revealed that most of the AURKB activity localized to the center of the midbody (Fuller *et al.* 2008). These authors suggest that the spindle or spindle-associated proteins are responsible for activating AURKB. Although a previous study indicated that PGRMC1 is associated with the mitotic spindle (Nousiainen *et al.* 2006), the role of PGRMC1 in activating AURKB during mitosis and meiosis can be only hypothesized and considerably more studies must be conducted to resolve this issue.

In addition, PGRMC1 may be involved in meiotic events that precede polar body formation, as the present data demonstrate that PGRMC1 associates with chromatin and colocalizes with AURKB at metaphase I and metaphase II. AURKB is a component of the CPC, which in part consists of the INCENP, to which AURKB is physically associated (Ruchaud *et al.* 2007). Furthermore, altered AURKB expression has been suggested to increase the frequency of nondysjunction and aneuploidy in mammalian oocytes (Vogt *et al.* 2009) while an overexpression prevents chromosome misalignment during meiosis of mouse oocytes (Shuda *et al.* 2009). Collectively, these findings are consistent with the concept that the interaction between PGRMC1 and AURKB plays a role in AURKB's ability to promote homologous chromosome alignment and segregation.

This concept is supported by two observations. First, the present work demonstrates that PGRMC1 concentrates at foci on the chromatin of prometaphase I-staged oocytes and at this time, AURKB starts to be phosphorylated. As meiosis progresses, both PGRMC1 and the phosphorylated form of AURKB become concentrated on the centromeric region. Since pharmacological inhibition of AURKB activity leads to abnormal chromosome congression and alterations in the formation of the chromosomal plate (Swain *et al.* 2008, Vogt *et al.* 2009), this implicates that PGRMC1–AURKB interaction is involved in the mechanism by which chromosomal separation is mediated.

The second and probably more important observation supporting a functional role for PGRMC1 in oocyte meiotic maturation is provided by the PGRMC1 antibody injection study. In this study, PGRMC1 antibody injection at GV stage results in the improper positioning of the chromatin, affecting the ability of the chromosomes to condense properly and resolve bivalents. While these observations support a role for PGRMC1 in meiosis, they also demonstrate the need to define the exact nature of the relationship between PGRMC1 and active AURKB.

This study also supports the hypothesis that changes in the level of PGRMC1 expression or its genetic structure could predispose oocytes to undergo abnormal meiotic division, which would lead to errors in chromosome segregation and ultimately aneuploid embryos. Interestingly, there are at least two conditions in women in which PGRMC1 is altered. The first is a reduction in the level of PGRMC1 expression observed in women with an X;autosome translocation (i.e. [t(X;11)(q24;q13)]). This X chromosome translocation likely depletes one copy of *PGRMC1*, thereby accounting for the reduced level of PGRMC1 in these women (Mansouri *et al.* 2008). The second condition involves a single base mutation in which the histidine at residue 165 is changed to arginine. Although this mutation does not change the level of PGRMC1 expression, it does reduce its functional activity by ~50% (Mansouri *et al.* 2008). Both of these genetic alterations in PGRMC1 are detected in woman with premature ovarian failure (Mansouri *et al.* 2008). Whether these alterations in PGRMC1 expression or genetic structures adversely affect the functional capacity of the oocyte remain to be determined.

In summary, these data demonstrate that PGRMC1 is expressed in bovine oocytes, zygotes, and blastocysts. Our data also suggest an important role for PGRMC1 in oocyte maturation that may be specifically related to the mechanism by which chromosomes segregate and the first polar body extruded. This study also implies that PGRMC1 and AURKB interact at specific points in the meiotic cascade to ensure that errors in spindle formation, chromosome segregation, and cytokinesis do not occur. These possibilities are currently under investigation.

Materials and Methods

Oocyte collection and culture

All the chemicals used in this study were purchased from Sigma Chemical Company except for those specifically mentioned. Bovine ovaries were recovered at the abattoir (IT 2270M CE, INALCA JBS S.p.A., Ospedaletto Lodigiano, LO, Italy) from pubertal females subjected to routine veterinary inspection and in accordance to the specific health requirements stated in Council Directive 89/556/ECC and subsequent modifications. Ovaries were transported to the laboratory within 2 h in sterile saline (NaCl, 9 g/l) maintained at 26 °C. All subsequent procedures, unless differently specified, were performed at 35–38 °C. Cumulus–oocyte complexes (COCs) were retrieved from mid-sized antral follicles (2–6 mm) with a 16-gauge needle mounted on an aspiration pump (COOK-IVF, Brisbane, QLD, Australia). COCs were washed in TCM-199 supplemented with HEPES buffer (20 mM HEPES, 1790 U/l heparin, and 0.4% of BSA) and examined under a stereomicroscope. Only COCs medium-brown in color, with five or more complete layers of cumulus cells with oocytes with finely granulated homogenous ooplasm, were used.

Groups of 25–30 COCs were *in vitro* matured in TCM-199 supplemented with 0.68 mM L-glutamine, 25 mM NaHCO₃, 0.4% BSA fatty acid free, 0.2 mM sodium pyruvate, and 0.1 IU/ml of recombinant human FSH (Gonal-F, Serono) in humidified air under 5% CO₂ at 38.5 °C as previously described (Luciano *et al.* 2005). Oocytes were mechanically separated from cumulus cells either just after collection from ovaries (immature oocytes at GV stage) or after 4, 8, 12, 16, 20, and 24 h of culture.

IVF and embryo culture

After 24 h of *in vitro* maturation, oocytes were fertilized as previously described (Luciano *et al.* 2005). Briefly, the content of a straw of cryopreserved bull spermatozoa (CIZ, S Miniato, Pisa, Italy) was thawed and cells were separated on a 45–90% Percoll gradient. Sperms were counted and diluted to a final concentration of 0.5×10^6 spermatozoa/ml in fertilization medium that was a modified Tyrode's solution (TALP) supplemented with 0.6% (w/v) BSA fatty acid free, 10 µg/ml heparin, 20 µM penicillamine, 1 µM epinephrine, and 100 µM hypotaurine. COCs and sperms were incubated for 18 h at 38.5 °C under 5% CO₂ in humidified air. After IVF, presumptive zygotes were washed and cumulus cells were removed by vortexing for 2 min in 500 µl of a modified synthetic oviduct fluid (SOF; Tervit *et al.* 1972) supplemented with 0.3% (w/v) BSA fraction V, fatty acid free, MEM essential and nonessential aminoacids, 0.72 mM sodium pyruvate, and buffered with 10 mM HEPES and 5 mM NaHCO₃. Presumptive zygotes were rinsed and transferred in embryo culture medium, which was SOF buffered with 25 mM NaHCO₃, supplemented with MEM essential and nonessential aminoacids, 0.72 mM sodium pyruvate, 2.74 mM myo-inositol, 0.34 mM sodium citrate, and 5% calf serum (Gibco and Invitrogen). Incubation was performed at 38.5 °C under 5% CO₂, 5% O₂, and 90% N₂ in humidified air. Zygotes and blastocyst-stage embryos were collected after 18 and 196 h post insemination respectively (Lodde *et al.* 2009).

Western blot analysis

Freshly isolated COCs were denuded by vortexing in 500 µl TCM-199 supplemented with 20 mM HEPES and 5% calf serum (Gibco, Invitrogen, and Life Technologies) for 2 min at 35 Hz. Oocytes (500–700 per extracts) and aliquots of 50 mg ovarian cortex were homogenized in lysis buffer (10 mM Tris-Cl, pH 4, 1% w/v NP-40, 150 mM NaCl, 10 mM EDTA, and 0.2% Zwitterion), which were supplemented with complete protease inhibitor cocktail and incubated for 1 h on ice then centrifuged at 14 000 g for 15 min. The supernatant was then mixed with 4× SDS–Laemmli loading buffer and extensively boiled for 15 min. After centrifugation for 5 min at 14 000 g, each cell extract was loaded onto 12% acrylamide gel and transferred to nitrocellulose. The nitrocellulose was then incubated with 5% nonfat dry milk powder overnight at 4 °C to saturate nonspecific sites. The nitrocellulose blot was incubated with polyclonal rabbit anti-PGRMC1 (Prestige antibodies, Sigma) for 2 h at room temperature at a dilution of 1:500. Western blots were processed using an

HRP-conjugated anti-rabbit secondary antibody (1:2000) for 45 min at room temperature and developed using HRP Immuno-Blot Assay kit (Bio-Rad Laboratories).

Immunofluorescence staining

Indirect immunofluorescence staining was carried out to evaluate the cellular localization of PGRMC1, AURKB, and AURKB phosphorylated on Thr232 (phospho-Thr²³² AURKB) in oocytes at different stages of meiosis (see Table 1). All the oocytes and the zygotes were freed of cumulus cells by vortexing. Then the zona pellucida was removed from the oocyte, zygotes, and embryos using 0.5% pronase as previously described (Modina *et al.* 2004). After being washed three times in PBS containing 0.1% polyvinylalcohol (PBS–PVA), the oocytes, the zygotes, and the embryos were fixed in 4% paraformaldehyde in PBS for 15 min at 37 °C, and then transferred at 4 °C for the next 45 min. The fixed oocytes, zygotes, and embryos were washed three times with PBS–PVA and permeabilized with 0.3% Triton-X 100 in PBS for 10 min at room temperature. Nonspecific binding was blocked by incubating the samples in 10% donkey serum and 1% BSA in PBS for 30 min at room temperature. The samples were then incubated with the primary antibody overnight at 4 °C. PGRMC1 immunolocalization was carried out using a rabbit polyclonal anti-PGRMC1 antibody (Prestige antibodies by Sigma). For the colocalization study, the oocytes were incubated either with a solution of rabbit polyclonal anti-PGRMC1 antibody and mouse monoclonal anti-AURKB antibody (Abcam, Cambridge, UK) or with a solution of mouse monoclonal anti-AURKB antibody and rabbit polyclonal anti-phospho-Thr²³² AURKB antibody (BioLegend, San Diego, CA, USA). All the primary antibodies were diluted 1:50 in PBS containing 1% BSA. After being washed three times in PBS–PVA for 10 min each, the oocytes were incubated with TRITC-labeled donkey anti-rabbit antibody (dilution 1:100; Vector Laboratories, Inc., Burlingame, CA, USA) or, for the colocalization experiment, with a solution of Alexa Fluor 488-labeled donkey anti-mouse antibody (dilution 1:500; Invitrogen and Life Technologies) and TRITC-labeled donkey anti-rabbit antibody for 30 min at room temperature.

The samples were washed three times in PBS–PVA and mounted on slides in the antifade medium Vecta Shield (Vector Laboratories, Inc.) supplemented with 1 µg/ml DAPI. Samples were analyzed on a Nikon Diaphot epifluorescence microscope or on a Nikon C1si confocal laser-scanning microscope (Nikon Corp., Tokyo, Japan). In each experiment, negative controls were performed by adding an equal concentration of rabbit IgG (Vector Laboratories) or omitting the primary antibodies and did not reveal any staining.

PGRMC1 blocking antibody injection study

The anti-PGRMC1 antibody (Prestige antibodies by Sigma) was spin dialyzed and concentrated using 10 kDa Millipore Ultrafree 0.5 PBGC filter unit (Millipore Corp., Bedford, MA, USA). GV-stage oocytes within their cumulus cell complexes were injected with 15–35 pl of a 1.2 mg/ml stock solution of

anti-PGRMC1 antibody in PBS. This resulted in a final concentration of 0.15–0.30 μ M of antibody in the oocyte. The injected volume represented $\sim$ 1.5–3% of oocyte volume. As control, a group of COCs in each experiment was injected with an equal volume of rabbit IgG (Vector Laboratories), dissolved in PBS at the same concentration or PBS only. The procedure was carried out as previously described in mouse (Mehlmann *et al.* 2002, Jaffe & Terasaki 2004) and adapted to bovine oocyte volume.

A microinjection apparatus (Narishige Co. Ltd, Tokyo, Japan) was used to guide the holding and injecting micropipettes into a 50 μ l drop of TCM-199–HEPES buffer covered with mineral oil. The injecting pipette was connected to a FemtoJet (Eppendorf Srl, Milano, Italy) that allowed the injection of minute quantities of solution.

After being injected, COCs were washed in TCM-199–HEPES buffer and matured *in vitro* for 24 h as described above. After the maturation time, the oocytes were freed of cumulus cells and fixed in 500 μ l of 60% methanol in PBS for 30 min at 4 °C. The oocytes were stained with 0.5 mg/ml of propidium iodide to assess the stage of meiotic progression by observation at $\times$ 200–400 under fluorescence microscopy (Luciano *et al.* 2005).

Statistical analysis

All experiments were replicated at least three times. Observations from all the experiments were pooled. The images shown in each figure are representative. The actual number of oocytes at each stage of maturation, which were analyzed, is provided in the legend of each figure. Differences in maturation rate in the PGRMC1 blocking antibody injection study were analyzed by χ^2 -test. Probabilities of <0.05 were considered statistically significant.

Supplementary data

Declaration of interest

The authors declare that there is no conflict of interest that could be perceived as prejudicing the impartiality of the research reported.

Funding

This work is supported by Programma dell'Università per la Ricerca (PUR) 2008, grant number 12-1-5284002-27 (AML), University of Milan.

Acknowledgements

The authors are grateful to Mrs Elisa Zuccari for excellent technical assistance. The authors would also like to thank Prof. Cristiano Rumio of the Department of Human Morphology, University of Milan for excellent support for LSCM.
