(Received 11th March 1969)

Summary. Luteal tissue slices from an African elephant in early pregnancy have been shown to synthesize progesterone from added pregnenolone. The percentage conversion (2.4%/100 mg luteal tissue/hr) is very much lower than that found for human, bovine and porcine corpora lutea. It was possible to isolate a small amount of progesterone (0.18 µg/g) from a large quantity of luteal tissue taken from another pregnant elephant; this is far below the values found in the active corpora lutea of all other mammals.

The reasons for the relative inability of elephant corpora lutea to synthesize progesterone are not known. The elephant may be extremely sensitive to the action of progesterone, or the hormone may not be necessary for normal reproduction in this species.

INTRODUCTION

Previous studies on the corpora lutea of the African elephant, Loxodonta africana, failed to demonstrate the presence of any progesterone in this tissue. Corpora lutea from five animals in early, mid and late pregnancy and from three non-pregnant animals at various stages of the oestrous cycle contained less than 0.1 to 0.2 µg progesterone/g luteal tissue (Short & Buss, 1965; Short, 1966), whereas the concentrations in the functional corpora lutea of other mammals range from about 10 to 100 µg/g tissue.

The purpose of the present investigation was two-fold; firstly to see whether fresh elephant luteal tissue contained the enzyme systems necessary for the conversion of pregnenolone (3β-hydroxypregn-5-en-20-one) to progesterone, and secondly to see whether progesterone could be isolated from a large pool of elephant corpora lutea.

MATERIALS AND METHODS

Incubation studies

A 43-year-old female elephant, whose age was estimated from the degree of molar tooth wear (Laws, 1966), was shot in the Luangwa Valley, Zambia. The animal was lactating with a calf estimated to be about 2 years old at foot,
and was pregnant with a 1590-g (34-lb) male foetus in the left uterine horn. The estimated gestation age calculated from the data of Perry (1953) was about 7 months, the total length of gestation being about 22 months. The left ovary contained one 30-mm diameter corpus luteum and fifteen brown, regressed corpora lutea. The right ovary contained one 35-mm diameter corpus luteum which was used for the incubation study, three other corpora lutea of 23-, 17- and 16-mm diameter, and eight brown, regressed corpora lutea.

The ovaries were removed within 13 min of death, placed on ice in a thermos flask, and flown immediately to Chilanga. On arrival in the laboratory, the largest corpus luteum was dissected out of the right ovary and cut into thin slices. Incubation flasks were then set up as shown in Table 1.

The [7α-3H]pregnenolone added to flasks 1 and 3 had a specific activity of 500 mCi/m-mole (1.58 mCi/mg; The Radiochemical Centre, Amersham, Bucks.) and was used without any pre-purification. The elephant serum was obtained by collecting freshly flowing jugular vein blood from the same elephant. The blood was allowed to stand until a clot had formed, the serum that was removed from it being decanted into a sterile bottle.

Incubations were carried out for 1 hr at 37° C in air and were started 4 hr 10 min after the death of the elephant. At the end of the incubation, 50 ml absolute ethanol were added to each flask and the samples were then flown to Cambridge and subsequently stored at −20° C until they could be extracted. Immediately before extraction, 0-01 µCi, 0-072 µg [4-14C]progesterone was added to each flask, followed by 50 ml absolute methanol. Following homogenization in methanol, the pooled methanolic extracts were evaporated to about 10 ml, diluted with distilled water, and extracted with ethyl acetate; the extract was then evaporated to dryness. After partitioning between petroleum ether and 70% aqueous methanol, the methanolic extracts were evaporated to dryness and chromatographed on paper in a ligroin/80% methanol system, together with a standard of authentic progesterone.

The paper chromatograms were run through a windowless gas-flow strip scanner (Frieske & Hoepfner), and the zone corresponding to progesterone was eluted. Thirty mg of authentic progesterone were added to the eluate as carrier and the progesterone was recrystallized from various solvents. After the third re-crystallization, the crystals from the experimental flask were dissolved in absolute methanol and reduced with sodium borohydride. Chromatography of the reaction product showed that the major compound had the
$R_f$ value of 20β-hydroxypregn-4-en-3-one. The reaction product was then recrystallized a further three times from various solvents. Aliquots of all crystals and mother liquors were taken for counting, and the 14C:3H ratios determined.

A similar procedure was carried out with the medium control, except that the progesterone was recrystallized to constant 14C:3H ratios without derivative formation.

**Isolation studies**

A female elephant, aged 14$\frac{1}{2}$ years as judged by the criteria of Laws (1966), was shot in the Mkomasi cropping scheme in Northern Tanzania. The animal was not lactating, but was pregnant, probably for the first time, and contained a 105-g female foetus with an estimated gestation age of less than 4 months (Perry, 1953). The ovaries were removed within $\frac{1}{2}$ hr of death and frozen until they could be dissected. Numerous corpora lutea were present, and they were dissected out and placed in a large volume of ethanol. On arrival in Cambridge, the sample was stored at +5°C until extraction.

The luteal tissue was first weighed (36.6 g) and after the addition of 0.5 µCi, 0.0135 µg [7α-3H]progesterone, it was thoroughly homogenized first in the ethanol in which it had been stored and then in methanol. The pooled alcoholic extracts were evaporated to a small volume, and cooled to −20°C overnight. After filtration, the precipitate was removed, and the filtrate was diluted with distilled water and then extracted with ethyl acetate.

The dried ethyl acetate extracts were treated with Girard’s reagent T and separated into ketonic and non-ketonic fractions (Pincus & Pearlman, 1941); the non-ketonic fraction was discarded. The ketonic fraction was partitioned between petroleum ether and 70% methanol and the methanolic fraction was chromatographed on paper. The progesterone zone was eluted, treated with a few drops of acetic anhydride and pyridine (1:1) overnight, and re-chromatographed on paper. After eluting the progesterone area, 1/10- aliquots were removed for liquid scintillation counting and for gas chromatography. The remaining four-fifths were treated with 20β-hydroxysteroid dehydrogenase (Henning & Zander, 1962), and the reaction product re-chromatographed on paper with a standard of 20β-hydroxypregn-4-en-3-one. After elution, half the eluate was used for counting and gas chromatography, whilst the remainder was acetylated overnight with acetic anhydride and pyridine, re-chromatographed on paper, and the 20β-acetoxy pregn-4-en-3-one zone finally eluted, counted and quantitated by gas chromatography. All the results were corrected for extraction losses.

**Radio-active counting procedures**

Samples were counted in a Packard Tricarb Model 3003 Liquid Scintillation Counter. The counting efficiencies in the two channels used were: Channel 1, 3H, 30.3%; 14C, 15.0%; Channel 2, 3H, 0%, 14C, 52.4%. The scintillator used throughout was prepared by dissolving 5 g PPO and 0.3 g dimethyl POPOP in 1 litre redistilled A.R. toluene.
Gas chromatography

This was carried out in an F & M model 400 instrument with a 4 ft column of 3.8% S.E. 30 on Diaoport S 80 to 100 mesh, at a temperature of 225° C. Quantitation was achieved by using an internal standard of 20β-acetoxypregn-4-en-3-one or progesterone as appropriate. Peak areas were recorded by cutting out and weighing the tracings produced by the chart recorder.

RESULTS

Incubation studies

Table 1 shows that only a small proportion of the added pregnenolone was converted to progesterone by luteal tissue in the 1-hr incubation period. A trace of progesterone was also detected in the medium control, to which no tissue had been added. This could have been due to contamination of the original sample of [7α-3H]pregnenolone with progesterone.

Most of the remaining radio-activity in the experimental flask appeared to be unchanged pregnenolone, as judged by its RF value on the paper chromatogram before and after acetylation.

Table 2 shows that the progesterone formed by the luteal tissue was re-crystallized to a constant $^{14}$C:$^3$H ratio, which remained virtually the same after derivative formation. There can be no doubt, therefore, that elephant luteal tissue does possess the enzyme systems necessary to convert pregnenolone to progesterone.

Isolation studies

Progesterone appeared to be present in the large pool of luteal tissue (36.6 g) at a concentration of 0.18 µg/g. Since there was too little steroid available for further characterization by procedures such as infra-red or nuclear magnetic resonance spectroscopy, the specific activity of various derivatives was measured. Since the specific activity of the radio-active [7α-3H]progesterone added at the beginning of the extraction was $2 \times 10^6$ counts/min/µg, the lower
specific activities shown in Table 3 suggest that progesterone was definitely present in the extract. The fact that the specific activity remained relatively constant after the formation of two derivatives could be taken as reasonable evidence for the isolation of progesterone from elephant corpora lutea. However, the concentration found even at this very early stage of pregnancy was exceedingly low.

An internal isotope standard of [7α-3H]progesterone (0.5 µCi, 0.0135 µg) was added at the beginning of the extraction procedure.

**DISCUSSION**

Pregnenolone is normally converted to progesterone in very high yield by luteal tissue in a variety of different mammals. Duncan, Bowerman, Hearn & Melampy (1960) found that pig luteal slices incubated in a Krebs Ringer bicarbonate buffer with glucose converted up to 74% of pregnenolone to progesterone in 2 hr, even when the amount of pregnenolone added was as great as 794 µg/g luteal tissue. Ryan & Smith (1965), using slices of human corpus luteum, found an almost complete conversion of pregnenolone to progesterone and other steroids in 4 hr. Armstrong & Black (1966) found that even regressing bovine corpora lutea, collected on Days 19 to 21 of the oestrous cycle, retained the ability to synthesize large amounts of progesterone from added pregnenolone. The granulosa cells of the mare can even convert pregnenolone to progesterone in high yield before they have begun to luteinize (Short, 1964).

The incubation study described here has demonstrated that although elephant luteal tissue does contain the enzyme systems necessary for converting pregnenolone to progesterone, the percentage conversion after a 1-hr incubation was only 2.4%. Most of the radio-activity could be accounted for as unchanged pregnenolone. This finding is in keeping with the very small amount of progesterone detected in elephant luteal tissue, 0.18 µg/g. This amount would have been at the limit of sensitivity of the assay procedure in our previous studies, when we failed to detect progesterone in elephant corpora lutea collected from animals at various stages of the oestrous cycle and pregnancy (Short & Buss, 1965; Short, 1966).

Table 4 lists the maximum concentrations of progesterone found in the corpora lutea of a wide variety of mammals, including the Hyrax, which is
often regarded as the closest living relative of the elephant. The concentrations in all these species are at least 40 times higher than the concentrations in elephant corpora lutea. One explanation may be that the elephant is extremely sensitive to the action of steroid hormones; however, in male elephants the concentration of testosterone in testicular tissue is similar to that of other mammals (Short, Mann & Hay, 1967). A more exciting possibility is that progesterone is not an essential hormone of reproduction in the elephant.

ACKNOWLEDGMENTS

We would like to thank R. Langerveld for shooting the elephant in the Luangwa Valley, and the Director of the Department of Game and Fisheries in Zambia for providing the aircraft to fly the fresh material to Chilanga. W. R. Carr of the A.R.C. of Zambia assisted with the incubation experiment. Dr R. M. Laws kindly provided the corpora lutea from the elephant shot in the Mkomasi cropping scheme in Tanzania, and we are most grateful to the Wellcome Trust for financial support.
