(Received 7th February 1972)

Summary. No increase in the growth rate of Vibrio fetus var. venerealis was observed in a series of growth trials in which different concentrations of erythritol, FSH, oestrone and progesterone were added to liquid culture medium. A significant increase in the growth rate was observed \(P<0.05\) when inverse concentrations of oestrone and progesterone were incorporated into the same medium with concentrations of oestrone being higher than those of progesterone.

INTRODUCTION

The presence of potential substrates for bacteria in the lumen of the reproductive tract of the cow was reported by Olds & VanDemark (1957). Hawk, Simon, Cohen, McNutt & Casida (1955) noted an apparent hormonal regulation of the uterine bacterial defence mechanism. A study of the enhanced response in vitro of V. fetus to separate additions of progesterone, corpus lutum extract or testosterone to thioglycollate broth led Osborne & Bourdeau (1955) to suggest a possible hormonal influence on the course of V. fetus infection in the cow. Stimulation of the growth in vitro of V. fetus in the presence of 17-β-oestradiol (0.005%) was described by Zemjanis & Hoyt (1960).

The presence of erythritol in uterine tissues and fluids of the cow was described by Keppie, Williams, Witt & Smith (1965), not only as a factor in the tissue localization of the Brucellae, but also as a growth factor for these organisms. The possibility of erythritol as a growth factor for V. fetus was suggested by M. Herzberg (personal communication, 1966). However, erythritol failed to stimulate the growth in vitro of V. fetus var. intestinalis and apparently is not involved in the tissue localization of this organism (Lowrie & Pearce, 1970).

The present study was undertaken to determine the response in vitro of V. fetus var. venerealis to different concentrations of erythritol, FSH, oestrone and progesterone when individually added to a basal medium. The combined

effects of inverse concentrations of oestrone and progesterone on the growth of *V. fetus* var. *venerealis* were also considered.

**MATERIALS AND METHODS**

**Vibrio isolant**

The organism used was a smooth fresh isolant of *V. fetus* var. *venerealis* previously identified by the criteria of Florent (1963) and Lecce (1958). To avoid the use of repeated subcultures of the isolant, 24- to 48-hr-old cultures in Brucella broth (Pfizer Diagnostic Division, New York) were stored at −70°C. These cultures were used to develop primary inocula.

**Basal medium for growth**

Brucella broth was used for each trial. Brucella broth with 0.16% agar added was used to prepare seed inocula for the tests. All media were sterilized at 121°C for 15 min. All cultures were incubated at 37°C.

**Gas atmosphere required for growth**

The cultures in test and control nepheloflasks were incubated in an atmosphere of 10% CO₂, 85% N₂ and 5% O₂. The gas mixture was commercially prepared (Airco Inc., Jacksonville, Florida). It was sterilized by passage through a glass cylinder packed with glass wool. Each end of the cylinder was closed with a rubber stopper through which glass tubing was passed. A glass-tipped rubber tube delivered the gas into the inoculated flask. The entire assembly was sterilized at 121°C for 15 min. The gas mixture was passed into each flask for a period of 30 sec at a flow rate of 2 lb/in² and the flask was then sealed with a black rubber stopper. Seed cultures were prepared by the method described by Lovell (1964).

**Growth factors studied**

The growth factors studied were 1-erythritol, porcine FSH (Mann Research Laboratories Inc., New York), oestrone (1,3,5,(10)-estratrion-3-ol-17-one) and progesterone, USP (Matheson, Coleman and Bell Inc., East Rutherford, New Jersey).

**Preparation of test inocula**

Seed cultures of *V. fetus* were prepared in 30 ml Brucella broth with added agar. These were propagated in a Model G Incubator-Shaker (New Brunswick Scientific Co., New Brunswick, New Jersey) at 100 oscillations/min. Each culture was checked for motility, morphology and purity after a 36-hr incubation period. The cells were synchronized by passage through five layers of sterile Whatman Number 40 filter paper. A 5-ml inoculum of broth culture was used for each trial.

**Trial 1. Erythritol**

Duplicate nepheloflasks of erythritol concentrations of 0.06, 1.0, 3.0, 5.0 and 10.0 mg/ml were prepared aseptically in Brucella broth from membrane-
filtered (Millipore Filter Corporation, Bedford, Mass.) crythritol stock solutions of 50% (w/v) and 3% (w/v). A nepheloflask of Brucella broth was used as a colorimeter blank. Duplicate nepheloflasks of Brucella broth were set up as growth controls. Both test and control flasks were inoculated and the gas atmosphere was added. The optical density (OD) of each flask was read at time zero on a spectrophotometer (Bausch and Lomb Spectronic 20) at 525 nm. All the flasks were incubated in the shaker at 100 oscillations/min. The OD was read at 2-hr intervals until the organism reached the peak of the exponential growth phase. At this time, all the cultures were examined for purity. Graphs of OD against time were recorded for each test and control flask.

**Trial 2. Oestrone**

Duplicate nepheloflasks of oestrone concentrations of 0·01, 0·009, 0·007, 0·005, 0·003, 0·001 and 0·0005 g/100 ml were prepared aseptically in sterile Brucella broth from a 0·4% (w/v) stock solution of oestrone in analytical grade chloroform. Another series of flasks was similarly prepared for use as reagent blanks. Gentle steam heat was used to remove the chloroform from the broth, leaving the hormone in suspension. To assay the effect of trace amounts of chloroform on the growth of *V. fetus*, growth controls were prepared in chloroform-treated broth as well as in normal Brucella broth. The test and control flasks were inoculated and incubated as in Trial 1. The data were similarly collected.

**Trial 3. Progesterone**

A stock solution of progesterone (0·4% w/v) was prepared in analytical grade chloroform. The hormonal concentrations and methods were the same as those used in Trial 2.

**Trial 4. Combined inverse concentrations of oestrone and progesterone**

A series of three nepheloflasks was prepared for each concentration of the combined hormones. Volumes of the stock solutions used in Trials 2 and 3 were added to sterile Brucella broth to give final oestrone to progesterone concentrations of 0·001/0·009, 0·003/0·007, 0·005/0·005, 0·007/0·003 and 0·009/0·001 g/100 ml. Control cultures, reagent blanks and colorimeter blanks were prepared by the methods described in Trial 2. Inoculation, incubation and data collection were performed as previously described (Trial 1).

**Trial 5. FSH**

A stock solution of FSH (0·5% w/v) was prepared in sterile distilled water. Hormone concentrations of 0·01, 0·005, 0·003, 0·001 and 0·0005 g/100 ml were prepared in sterile Brucella broth in triplicate. The trial was completed by the methods described in Trial 1.

**Data analyses**

The slopes of the growth curves and the mean change in OD per unit time were derived for each trial. The data were examined for statistical differences.

between the test and control growth curves by a one-way analysis of variance with equal replication and Duncan’s multiple range test (Steel & Torrie, 1960).

**RESULTS**

Mean changes in OD per unit time and the slope means for each trial are given in Table 1. The results of statistical examination of the data are given in Table 2. No significant differences ($P<0.05$) were found between the test and control growth curves established in trials of erythritol, oestrone, progesterone and FSH.

Significant differences were found among the results of the oestrone—progesterone trial (No. 4). Samples of some hormonal concentrations were significantly different from the hormone-free controls ($P<0.05$). No significant difference was found among concentrations of oestrone/progesterone of 0.005/0.005, 0.007/0.003 and 0.009/0.001 g/100 ml, although these were significantly different from the hormone-free controls. No significant difference was determined between oestrone/progesterone concentrations of 0.001/0.009 and 0.003/0.007 g/100 ml and the hormone-free controls.

All cultures were found to be pure on routine check after each trial.

The use of chloroform as a vehicle for the steroid hormones and its subsequent removal as described had no effect on the growth of *V. fetus* ($\text{calc}^1 = 1.0; 0.05^1 = 6.314$).

**DISCUSSION**

The study of bacterial growth rate based on OD rather than on the use of viable cell counts was found to be of value by Lyon, Hall & Costas-Martinez (1970). The reliability of the OD method of growth study improves with the use of synchronized cultures (Wilson & Miles, 1964) which allow the increase in OD of the culture to be proportional to the increase in cell numbers. This proportionality ceases to be a linear function when the OD reading exceeds 0.4 (Anon., 1957). For this reason, the slopes derived in all the trials were calculated from points obtained during the exponential growth phase at an OD of less than 0.4. Turbidimetric studies for potential growth factors for *V. fetus* were used by Trueblood & Tucker (1957) and Reich, Dunne, Bortree & Hokanson (1957).

The metabolism of *V. fetus* was determined to be microaerophilic by May (1953). Alexander (1957) demonstrated a lack of fermentative ability for *V. fetus*. Biochemical and serological differences were reported between *V. fetus* var. *venerealis* and *V. fetus* var. *intestinalis* (Florent, 1963; Walsh & White, 1968). These differences deserve emphasis if progress is to be made in further studies of *V. fetus* metabolism. A common feature of the metabolism of both varieties of *V. fetus* is an apparent failure to utilize most carbohydrates as substrates. Erythritol failed to stimulate the growth of *V. fetus* var. *intestinalis* (Lowrie & Pearce, 1970) and the present study indicates a similar lack of activity in the metabolism of *V. fetus* var. *venerealis*. The possibility of erythritol as a tissue localizing factor for *V. fetus* var. *venerealis* in the uterus and cervix of the cow is thus rather remote.
The growth increase due to an oestrogenic compound noted by Zemjanis & Hoyt (1960) was not observed in this study. Not only oestrone but also progesterone and FSH were without effect. Osborne & Bourdeau (1955) observed improved growth rates when hormone-containing tissue extracts were added to culture medium. The presence of more than one tissue localizing factor in vivo was suggested by Lowrie & Pearce (1970). The rôle of hormones in the tissue localization of bacterial species within the female reproductive tract remains to be defined.

The results of the oestrone–progesterone assay (Trial 4) showed a significant growth increase of V. fetus in those concentrations of oestrogen and progesterone in which the oestrone was in the greatest concentration. Hawk et al. (1955) found that oestrogen inhibited the growth in utero of Escherichia coli, but the uterine defence mechanism appears to be less effective against V. fetus (Black, Simon, Kidder & Wiltbank, 1954). In the intact animal, the combined effects of oestrogen and progesterone on the uterus are inseparable (Nalbandov, 1964). Trial 4 more closely simulated the conditions in vivo and may have provided for the hormones to act synergistically.

The use of studies in vitro to obtain a better understanding of the effects of potential substrates on the growth of V. fetus in the reproductive tract of the cow probably cannot duplicate similar studies in vivo. Further animal experimentation is needed to explain the extreme tissue localization of V. fetus var. venerealis in the reproductive tract of the cow. Such experimentation would lead to a greater understanding of V. fetus metabolism generally.
