SYNCHRONIZATION OF OESTRUS IN HEIFERS WITH IMPLANTS OF PROGESTERONE

J. F. ROCHE

The Agricultural Institute, Grange, Dunsany, Co. Meath, Ireland

(Received 8th February 1974)

Summary. Oestrus was synchronized in twenty-four of twenty-seven heifers with implants having a surface area of 9200 mm² and containing 4 g progesterone. Fertility following natural mating was low with only 47% of mated heifers conceiving. Neither the number of matings up to four nor the time of mating during oestrus increased the conception rate. Reducing the period of administration of progesterone from 20 to 10 days by giving 5 mg oestradiol benzoate on the day of insertion of the implants increased the conception rate to normal but resulted in a lowered oestrous response. Injection of 400 μg oestradiol benzoate 16 hr after removal of the implants following a 10-day treatment period did not increase the oestrous response but in fact lowered the conception rate compared to that of uninjected controls. Implants capable of synchronizing heat in heifers were less effective in cyclic dairy cows.

INTRODUCTION

The administration of exogenous progesterone to cows for the duration of a cycle suppresses oestrus and ovulation and the majority of cows show oestrus 2 to 5 days after withdrawal of the progesterone (Lamond, 1964). This method of synchronization of oestrus has been widely used, but the conception rate to matings at the controlled oestrus has been low (Hansel, 1967; Mauléon & Chupin, 1971). The use of more potent synthetic progestagens has not led to any improvement in fertility (Jochle, 1972).

The dominant rôle of progesterone in regulating the oestrous cycle has been confirmed by recent reports of blood levels of hormones throughout the oestrous cycle (Hansel, 1972). Because progesterone occurs naturally in many body tissues as well as in milk (Heap, Laing & Walters, 1973) and is also readily available, it is the progestagen of choice for synchronization of oestrus. The high daily amounts of progesterone required to suppress oestrus in cattle (Lamond, 1964) has hindered development of practical methods for synchronization. Silastic rubber implants impregnated with steroids are non-toxic and give a slow continuous release of steroids (Dziuk & Cook, 1966). Silastic implants impregnated with synthetic progestagens have been shown to be effective in controlling the oestrous cycle of heifers (Roche & Crowley, 1973). This paper deals with attempts to develop silastic implants capable of releasing sufficient progesterone to synchronize oestrus in cattle. Some factors affecting
conception rate to matings at the control heat were then examined in syn-
chronized heifers.

MATERIALS AND METHODS

Implants
Silastic implants were made up by incorporating 4 g progesterone into a 
silicone elastomer (Silcoset 105) and then adding a curing agent. Type I 
implants had a surface area of 9200 mm² while Type II implants had a surface 
area of 4100 mm². Implants were autoclaved and inserted into the dewlap 
with the aid of a trocar. They were removed by making a small skin incision 
and extruding the implant. Implants in the first experiment were weighed 
before and after insertion in attempts to determine the release rate of progester-
one in vivo.

Animals
The experimental animals, except in the last experiment, were Hereford cross 
mature non-pregnant heifers purchased locally. The heifers were grazed at pasture 
during the summer of 1972. Vasectomized bulls, fitted with chin-ball mating 
devices, were kept with the heifers to aid in the detection of oestrus. Beginning 
24 hr after removal of the implants, the heifers in all experiments were individu-
ally checked for oestrus every 4 hr for 36 hr with vasectomized bulls. Heifers 
in oestrus were mated to fertile bulls and killed 30 to 40 days later to determine 
the pregnancy rate based on presence of live embryos. Two animals in which 
resorbing embryos were found were classified as not pregnant.

Experiment 1
Twenty-seven heifers selected at random received Type I implants while 
fifteen similar animals received Type II implants. Vasectomized bulls were kept 
with the heifers for 20 days while the implants were in situ. Following removal 
of the implants, the number of animals in oestrus, the interval from removal 
of implants to onset of oestrus and the duration of oestrus were determined. 
Heifers exhibiting oestrus were mated to a fertile bull and then killed. In all 
subsequent experiments, only Type I implants were used.

Experiment 2
Thirty-three heifers received Type I implants for 20 days. Following removal 
of the implants, the heifers were randomly selected as they came into oestrus 
and mated from one to four times with fertile bulls at 4-hr intervals during 
oestrus and were subsequently killed.

Experiment 3
Fifteen heifers were randomly allocated to a short-term, and fifteen to a long-
term progesterone treatment. The short-term treatment consisted of exposure 
to a progesterone implant for 10 days with an injection of 5 mg oestradiol 
benzoate at time of insertion as described by Wiltbank & Kasson (1968), 
while the long-term treatment was the same as that described for the second
experiment. Heifers in oestrus following withdrawal of the implants were mated twice to fertile bulls, and the number that became pregnant was determined at slaughter.

Experiment 4
Forty-one heifers, ten of which were diagnosed as having inactive ovaries on the basis of rectal examination, received implants for 10 days and were given 5 mg oestradiol benzoate on the day of insertion of implants. Sixteen hours after removal of the implants, twenty-three heifers, selected at random, were given 400 µg of oestradiol benzoate in corn oil. The occurrence of oestrus was determined and the heifers were mated twice during oestrus to a fertile bull. The number pregnant was determined at slaughter.

Experiment 5
Fifty-nine cyclic Friesian dairy cows, 40 to 65 days after calving, received implants for 18 days. The animals were checked for oestrus twice daily at milking with the aid of a vasectomized bull during treatment. Following removal of the implants, the cows were then inseminated on a fixed-time basis without reference to behavioural oestrus.

Statistics
Differences between means were tested for significance by means of Student’s t test.

RESULTS

Experiment 1
None of the heifers was observed to have come into oestrus while the implants were in place. Following removal of Type I implants, the oestrous response was high compared with that obtained with Type II implants (Table 1).

The interval from removal of the implants to the onset of oestrus was shorter with Type I implants but the difference was not significant. There was no difference in the duration of oestrus. The conception rate following both treatments was low, only 47% of heifers conceiving following natural mating. Based on the weight difference between insertion and removal of the implants, Type I and Type II implants released $29 \pm 2.40$ and $17 \pm 0.95$ mg progesterone/day, respectively, and this difference was significant ($P<0.01$).

Experiment 2

Increasing the number of matings with the bull from one to four at 4-hr intervals during oestrus did not improve the conception rate (Table 2). It

was also evident that the time of mating during oestrus did not affect the conception rate since animals mated three or four times were served at different times during oestrus.

Experiment 3

The oestrous response in the heifers on the 10-day progesterone treatment was low (eleven of fifteen in oestrus), but the conception rate to mating of those heifers that did show oestrus was normal. This contrasted with the high
Synchronization of oestrus in heifers

Oestrous response (fourteen of fifteen in oestrus) and low conception rate in the heifers which received progesterone for 20 days. There were no differences in the interval from removal of the implants to the onset of oestrus or in the duration of oestrus between the two treatments.

**Experiment 4**

Injection of a small physiological dose of oestradiol benzoate (400 μg) 16 hr after removal of the implants following the short-term treatment with progesterone did not increase the oestrous response to the level obtained in the heifers with implants retained for 20 days in Exps 2 and 3 (Table 4). The conception rate was reduced however, in those heifers which received 400 μg oestradiol benzoate 16 hr after removal of the implants (Table 4).

**Experiment 5**

Insertion of Type I implants into cyclic dairy cows did not result in complete suppression of oestrus during the 18-day period of treatment. Of fifty-nine cows with implants, fourteen showed oestrus. The remaining forty-five cows were inseminated on a fixed-time basis. Cows that did not hold to the fixed-time insemination had repeat oestrous periods 18 to 23 days later. The treatment induced synchronization of oestrus in these forty-five cows with Type I implants.

**DISCUSSION**

The implants with the larger surface area were more effective in synchronizing oestrus than the implants with the same concentration of progesterone but half the surface area. This finding is in agreement with that of Dziuk & Cook (1966) who reported that surface area is more important than concentration in determining release rate from silastic implants. The large surface area required to release sufficient progesterone to suppress oestrus and ovulation,
even in heifers, does not favor the use of subcutaneous implants containing progesterone in cattle. If progesterone is to be used, alternative routes of administration will have to be investigated. Intravaginal pessaries containing progestagens, which are highly effective in sheep, have been used in cattle but the retention rate has been reported to be variable (Carrick & Shelton, 1967; Wishart & Hoskin, 1968; Mauléon & Chupin, 1971). More research is required to obtain pessaries with high retention rates (Scanlon, Sreenan & Gordon, 1972) or to develop intravaginal silastic implants similar to those used in humans (Mishell, Talas, Parlow & Moyer, 1970).

Despite the high degree of synchronization obtained with the present implants, the conception rate following natural mating was low and similar to results reported previously by others (Hansel, 1967; Mauléon & Chupin, 1970; Jochle, 1972). Many factors have been implicated in this low conception rate in cattle and sheep, such as poor sperm transport (Quinlivan & Robinson, 1969), increased 'breakage' of spermatozoa (Hawk & Conley, 1971), imbalance in the secretory pattern of hormones in plasma at this time (Hill, Lamond, Henricks, Dickey & Niswender, 1971; Rodeffer, Hopwood & Wiltbank, 1972), and low fertilization rate (Hill et al., 1971). It has been shown that rams placed with oestrous ewes at the time of pessary removal exhaust themselves in the first few matings. By ensuring that each oestrous ewe is hand-mated to a ram of high fertility, Jennings & Crowley (1972) have reported normal fertility in ewes induced to mate in late anoestrus. Hand-mating heifers from one to four times during oestrus in our experiments, however, did not improve the conception rate. It appears that cows differ from ewes in that high sperm numbers do not overcome the low conception rate obtained to matings at the controlled oestrus in synchronized animals. This apparent species difference emphasizes the difficulties that occur in extrapolating results from one species to another in relation to endocrine phenomena.

When oestrus was synchronized in heifers by feeding a progestagen for 9 days and injecting oestradiol valerate on the 2nd day of progestagen feeding to induce luteal regression, the conception rate was comparable to that in controls (Wiltbank & Kasson, 1968). Rodeffer et al. (1972) found that the pro-oestrous oestrogen peak occurred about 12 hr after the LH peak in heifers synchronized with progesterone for 18 days which was in marked contrast to the situation in control heifers or heifers synchronized after the 9-day treatment. Thus, abnormal oestrogen patterns may be a contributory factor in the low conception rate following an 18-day progesterone treatment. The results of these experiments using the 10-day treatment regimen support the fact that fertility is normal in heifers mated at the controlled oestrus. With the short-term treatment, however, the oestrous response was reduced from that obtained in similar heifers given progesterone for 20 days. The reasons for this lowered oestrous response are not immediately clear. It is possible that the oestrogen given to animals in the follicular stage of the oestrous cycle is either causing premature ovulation or that oestrogen is ineffective in causing complete luteal regression. Hansel (1972) claimed that single doses of oestradiol valerate have only a limited capacity to cause luteal regression and a decline in plasma progesterone in heifers. Neither Wiltbank & Kasson (1968) nor Wiltbank,
Synchronization of oestrus in heifers

Hawk, Hansel, Gordon, provided assistance. This required dairy cows to be synchronized when reduced to the 13th day of the cycle. Sturges, Wideman, Le Fever & Faulkner (1971), however, reported that the oestrous response was lower with the short-term treatment and thus the various progestagens could differ in this respect.

It has been shown that oestrogen is responsible for the release of the ovulatory surge of LH in cows (Hobson & Hansel, 1972). Small amounts of oestrogen given at the time of removal of the corpus luteum on Days 13 to 15 of the cycle in heifers also hastened the onset of oestrus and the LH surge as well as giving a shorter LH surge. Hansel (1972) also found that 400 µg oestradiol benzoate given 20 hr after the last feeding of 17-medroxyprogesterone acetate significantly hastened the onset of oestrus and also resulted in a normal conception rate. When 400 µg oestradiol benzoate were given to heifers 16 hr after removal of the implants in these experiments, the conception rate was reduced compared to that of synchronized heifers not receiving oestrogen after removal of implants. Reduced conception rates have been reported in ewes synchronized with preparations containing progestagens and oestradiol (Gordon, 1971) and in cattle when 2 mg oestrogen is given after a 9-day treatment with norethandrolone (Wiltbank et al., 1971). Whether changing the time of injection of oestrogen relative to implant removal would change the fertility level obtained has not been tested. If oestrogen is to be used after a progestagen treatment, then the dose and time of administration are both critical in determining conception rate.

The practical value of oestrous synchronization regimens depends on their effectiveness in lactating cows as well as in heifers. Silastic implants that are capable of synchronizing heat in cyclic heifers were not as effective in cyclic dairy cows. This would indicate that the dose of exogenous progesterone required to suppress oestrus in dairy cows is higher than that required in heifers. This could be due to the larger body size, but it is also possible that the endocrine interactions are different. Thus, synchronizing treatments effective in heifers may not necessarily be as successful in lactating dairy cows.
