Developmental patterns of enzymes in mouse testis

R.-S. Shen* and I. P. Lee

National Institute of Environmental Health Sciences, National Institutes of Health, Research Triangle Park, North Carolina 27709, U.S.A.

Summary. Study of the activities of hyaluronidase, lactate dehydrogenase isoenzyme-X and the dehydrogenases of sorbitol, α-glycerophosphate, glucose-6-phosphate, malate, glyceraldehyde-3-phosphate and isocitrate in the testes of mice of different ages showed that the changes were correlated with the stages of spermatogenic cell differentiation. The first 4 enzymes had activities which were low in newborn mice and high in adults; this pattern was reversed for the other enzymes.

Introduction

Studies of testicular enzymes have two main purposes: first, to determine enzyme activities in different cell types to understand biochemical changes during germ cell differentiation, and second, to use testicular enzymes as biochemical markers for elucidating control and regulatory mechanisms of spermatogenesis. The enzymes in rodent testes at different stages of development have been studied histochemically and biochemically. Hyaluronidase (E.C.3.2.1.35), sorbitol dehydrogenase (E.C.1.1.1.14), lactate dehydrogenase (isoenzyme-X) (E.C.1.1.1.27), hexokinase (sperm type) (E.C.2.7.1.1), cyclic nucleotide phosphodiesterase (E.C.3.1.4.17), 5′-nucleotidase (E.C.3.1.3.5), S-adenosyl-L-methionine decarboxylase (E.C.4.1.1.50) (see Gomes & VanDemark, 1974, for review), carnitine acetyltransferase (E.C.2.3.1.7) (Schanbacher, Gomes & VanDemark, 1974), and α-glycerophosphate dehydrogenase (E.C.1.1.1.8) (Schenkman, Richert & Westerfeld, 1965) first appear in spermatocytes or spermatids and then increase rapidly to reach maximum levels in spermatozoa when spermatogenesis is complete. The activities of γ-glutamyl transpeptidase (E.C.2.3.2.2.) (Hodgen & Sherins, 1973), β-glucuronidase (E.C.3.2.1.31), uridine diphosphatase (E.C.3.6.1.6), acid phosphatase (E.C.3.1.3.2) isoenzymes I and II, ornithine decarboxylase (E.C.4.1.1.17), glucose-6-phosphate dehydrogenase (E.C.1.1.1.49) (see Gomes & VanDemark, 1974, for review), and malate dehydrogenase (E.C.1.1.1.37) (Ambadkar & George, 1964) are highest in Sertoli cells, interstitial cells, or spermatogonia and then decrease gradually as spermatoctyes, spermatids and spermatozoa appear sequentially in the seminiferous epithelium.

In the present study, 8 enzymes were selected for quantitative determination of their activities during spermatogenic development in mice. They were hyaluronidase, sorbitol dehydrogenase, lactate dehydrogenase (isoenzyme-X), α-glycerophosphate dehydrogenase, malate dehydrogenase, glucose-6-phosphate dehydrogenase, isocitrate dehydrogenase (E.C.1.1.1.42) and glyceraldehyde-3-phosphate dehydrogenase (E.C.1.2.1.12).

Materials and Methods

Animals. Male CD-1 mice, 1–120 days of age, were used. After weaning, animals were housed five per cage with food and water freely available. The mice of three groups, each consisting of between

* Present address: Division of Biochemistry, Department of Human Biological Chemistry and Genetics, The University of Texas Medical Branch, Galveston, Texas 77550, U.S.A.
35 neonatal and 3 adult mice as the mice grew, were killed by decapitation or cervical dislocation. The testes were promptly removed, chilled on ice and weighed together. After taking samples for histological study, testes were homogenized (1:9 w/v) in ice-cold 10⁻² M-tris buffer, pH 7-0, containing 0·1 % cetyltrimethylammonium bromide. The crude homogenate was centrifuged at 9000 g for 30 min at 4°C, and the supernatant filtered through a Millipore filter (0·45 μm). This solution was used for enzyme assays. The epididymis and vas deferens were also removed from mice ≥ 20 days of age for enzyme studies.

**Enzyme assays.** All assays were performed in 3 groups and each group in triplicate at 32°C. The reagents used are shown in Table 1. Hyaluronidase was assayed by the method of Males & Turkington (1970) and lactate dehydrogenase (isoenzyme-X) by the method of Goldberg & Hawtrey (1967) using α-ketovalerate as substrate. The activities of sorbitol dehydrogenase, α-glycerophosphate dehydrogenase, glyceraldehyde-3-phosphate dehydrogenase, isocitrate dehydrogenase, glucose-6-phosphate dehydrogenase and malate dehydrogenase were determined by the methods published elsewhere (Bergmeyer, 1974). Enzyme activities were expressed as μmol of product formed/hr/mg protein.

**Protein determinations.** The total protein concentration of each supernatant was determined by the method of Lowry, Rosebrough, Farr & Randall (1951).

**Histology.** Testicular tissue samples were fixed in Bouin’s fluid for 24 hr, embedded in paraffin wax, and sections cut at 5 μm were stained with haematoxylin and eosin.

**Results**

**Testis weight.** Testicular weights increased slowly from 1 to 15 days of age. Maximum growth rates occurred between 20 and 40 days of age followed by a slower rate of growth until 120 days of age.

Changes in the activities of enzyme during development of the testis. The developmental patterns of these enzymes are shown in Text-fig. 1. Activities of hyaluronidase and lactate dehydrogenase
Isoenzyme-X were almost undetectable until 20 and 17 days of age, respectively, but they then rose markedly and remained unchanged between 40 and 120 days of age. Levels of sorbitol dehydrogenase and α-glycerophosphate dehydrogenase were detectable at 1 day of age; they increased rapidly until 40 and 35 days of age, respectively, and then remained at constant levels. The activities of glucose-6-phosphate, malate, glyceraldehyde-3-phosphate and isocitrate dehydrogenases were high at birth but had declined by 30 days of age. During adulthood, the levels of glucose-6-phosphate and malate dehydrogenases tended to decline, but those of glyceraldehyde-3-phosphate and isocitrate dehydrogenase remained unchanged.

Sorbitol dehydrogenase and glucose-6-phosphate dehydrogenase activities in testis, epididymis and vas deferens. These are shown in Text-figs 2(a) and 2(b). At the time when mature spermatozoa began to pass into the epididymis, the activity of sorbitol dehydrogenase had increased dramatically to a maximal value at 49 days of age, about 8 days after testicular activity had reached adult levels. This period coincides with that required for the spermatozoa to pass from the seminiferous tubules into the epididymis. Similarly, activity in the vas deferens was not detectable until 41 days of age and maximal values were reached only by 56 days of age, i.e. a 7-day lag associated with the passage of the first wave of spermatozoa through the vas deferens. The specific activities of sorbitol dehydrogenase in testis, epididymis and vas deferens in adult animals were 1.17, 3.92 and 0.87 μmol/mg protein/hr, respectively. The developmental patterns of glucose-6-phosphate dehydrogenase in the epididymis and vas deferens before 20 days of age are not shown because of the difficulty of obtaining enough tissue for enzyme assays. After 20 days of age, epididymal activity existed in two phases, with the transition point at about 38 days. The activity of this enzyme in the vas deferens was low and unchanged from 20 to 81 days of age. Specific activities of glucose-6-phosphate dehydrogenase in testis, epididymis and vas deferens were 1.89, 2.95 and 0.12 μmol/mg protein/hr, respectively, at 23 days of age, and 1.58, 0.75 and 0.12 μmol/mg protein/hr, respectively, at 40 days of age.
Histological differentiation of germ cell maturation. From 1 to 9 days of age there was little spermatogenic activity in the germinal epithelium, while at 13 days of age, there was an increase in tubule size and in the number of cells per tubule, probably due to an increase in the number of early primary spermatocytes. There was a progressive increase in tubule diameter from Days 17 to 60 and a concomitant increase in the cellular content of the germinal epithelium. Late primary spermatocytes were present at 17 and 21 days of age. Spermatids progressed from the cap phase at 27 days to the acrosome phase at 32 days of age, and spermatogenesis was complete by 42 days.

Discussion

Studies of testicular enzymes have been limited by the heterogeneity of spermatogenic cells in seminiferous tubules. Although efforts have been directed toward separation of the different spermatogenic cell populations (Lam, Furrer & Bruce, 1970; Go, Vernon & Fritz, 1971; Lee & Dixon, 1972; Meistrich, 1972), enzyme profiles of the specific cell types have not yet been established. Selection of testes at different stages of development before full spermatogenesis is achieved therefore offers an alternative for the study of testicular enzymes associated with spermatogenic cell types.

Two enzyme developmental patterns were distinguished in mouse testes during cellular differentiation. The activities of hyaluronidase, lactate dehydrogenase (isoenzyme-X), sorbitol dehydrogenase and α-glycerophosphate dehydrogenase changed from low to high levels, while those of glucose-6-phosphate, malate, glyceraldehyde-3-phosphate and isocitrate dehydrogenases changed from high to low levels as spermatogenesis proceeded. The two enzyme patterns crossed at puberty.

Activity of lactate dehydrogenase (isoenzyme-X) is first detectable at 17 days after birth. Since primary spermatocytes first appear at 15 days of age, the activities of this enzyme seem to be associated with spermatocytes. This conclusion is in agreement with that of Goldberg & Hawtrey (1967). Blackshaw & Elkington (1970) suggested that lactate dehydrogenase (isoenzyme-X) was linked to the first wave of pachytene primary spermatocytes in rats.

Hyaluronidase is not detectable by 20 days of age, indicating that it is not associated with spermatogonia or early spermatocytes. Appearance of activity as early as 23 days of age and the rapid increase in activity thereafter suggests its association with late spermatocytes and early spermatids. Males & Turkington (1970), however, reported that hyaluronidase activity first became detectable in rats with formation of the cap phase spermatids at 33–34 days of age.

The detection of sorbitol dehydrogenase activity in 1-day-old mice suggests that this enzyme might be present in the fetal testis. The close correlation of activity and testicular weight was similar to results obtained in rats by Mills & Means (1972).

The demonstration of α-glycerophosphate dehydrogenase activity in newborn mice also implies that this enzyme is associated with the differentiating spermatogonia. However, the increase in
activity from 1 to 35 days of age, as other spermatogenic cells appear in the seminiferous tubules, seems to indicate that this enzyme is also associated with more advanced germinal cells.

By histochemical methods, it has been shown that malate dehydrogenase in rats (Ambadkar & George, 1964), glucose-6-phosphate dehydrogenase in rats (Blackshaw & Elkington, 1970), and isocitrate dehydrogenase in mice (Hitzeman, 1962) are more active in interstitial cells than in the seminiferous tubules. Baillie (1961) calculated that >70% of the newborn mouse testis is interstitial tissue, and this decreases to 17, 6 and 4% on 7, 14 and 21 days of age, respectively. Hitzeman (1962) found that mitotic activity of the interstitial cells decreased in the neonatal mouse to stable levels by 15 days of age. Steinberger & Steinberger (1971) reported that proliferation of Sertoli cells in rat tissue ceased after Day 15. It is therefore possible that the decrease in activities of malate, glucose-6-phosphate and glyceraldehyde-3-phosphate dehydrogenases at 20 days of age may not only be due to the transformation of spermatocytes to spermatids but also to the relative decrease in the numbers of Sertoli and interstitial cells.

The results, suggesting that the first wave of mature spermatozoa is released into the epididymis at 37 days of age, agrees with data published by Gomes (1970) and Bruce & Meistrich (1972). The low epididymal glucose-6-phosphate dehydrogenase activity in adult mice reflects low activity in spermatozoa, as indicated by the extremely low activity in the vas deferens.
