Summary. Serum testosterone concentrations were elevated between 40 and 60 days p.c. but were low between 60 and 100 days p.c. when the testis descends. Elevated concentrations occurred in the perinatal period and from the 18th week after birth. Between 60 days p.c. and 16 weeks after birth the changes in serum testosterone concentrations parallel those of testicular development, as determined by morphology and steroid histochemistry, and peripheral LH concentrations.

Introduction

It is generally accepted that, in the testis, the interstitial (Leydig) cells are the principal source of the steroid hormone testosterone (Cooke, de Jong, van der Molen & Rommerts, 1972). In the pig these cells show a high degree of differentiation during three phases of life. The first phase is in the early fetal period during gonadal differentiation; the second phase is in the perinatal period; the third phase extends from puberty onwards (Allen, 1904; Moon & Hardy, 1973; van Straaten & Wensing, 1977). In each of these phases the testis shows marked positive hydroxysteroid dehydrogenase reactions (Moon & Raeside, 1972; Wrobel, Schilling & Dierichs, 1973; van Straaten & Wensing, 1978). In the pig (Booth, 1975), as in many other mammalian species (Attal, 1969; Resko, Feder & Goy, 1968; Challis, Kim, Naftolin, Judd, Yen & Benirschke, 1974), testosterone is one of the principal steroids produced in the fetal period. In the adult boar testosterone secretion appears to be quantitatively unimportant and the main androgens present in the blood are C\textsubscript{19}-16-unsaturated steroids (Gower, 1972; Ruokonen & Vihko, 1974; Booth, 1975). Nevertheless, the relatively small amount of testosterone present in the serum could be used as an indicator of testicular activity.

In the present investigation the concentrations of serum testosterone in male pigs during fetal and postnatal life were studied. The aim was to correlate these data with morphological and histochemical studies of the testis and with changes in serum LH concentrations and so lead to a better understanding of the development and function of the hypothalamo-hypophysial-gonadal system in this species.

Materials and Methods

Animals

The animals were all crossbred Dutch Landrace × Yorkshire. Blood samples were collected from 111 fetal male pigs ranging in age from 40 to 117 days post coitum. Samples were collected from the umbilical artery at laparotomy and hysterotomy of anaesthetized or slaughtered sows. Single blood samples were obtained from 38 boars aged between 0 and 5 weeks after birth. A further 8 males were used to obtain serial blood samples at approximately 2 week intervals between 6 and 25 weeks after birth. The blood samples from the postnatal pigs were taken from the jugular vein. Serum was stored at −20°C until assay.
Hormone determinations

Testosterone concentrations were determined by radioimmunoassay, using the antiserum and procedure described by Verjans, Cooke, de Jong, de Jong & van der Molen (1973). Samples were assayed in duplicate, using two different volumes of plasma (250 and 500 µl for the fetal and juvenile period, 100 and 200 µl for the perinatal and pubertal period). Testosterone was separated from 5α-dihydrotestosterone, which has a 50% cross-reaction with the antiserum, by chromatography on microcolumns of alumina (Verjans et al., 1973) or Sephadex LH-20 (cyclohexane: methanol: ethyl acetate, 75/12.5/12.5, by vol.). The sensitivity of the method was 20 pg/sample. Intra-assay variance, as calculated from the differences between the results of duplicate determinations, varied between 0-14 and 1-19 ng/ml, depending on the concentration in the sample (0-1 and 8-15 ng/ml, respectively). The interassay variance was 12.9% (coefficient of variation) at the level of 100 pg testosterone measured.

Analysis of variance of serum testosterone values for groups of animals at various ages was used to detect statistical differences.

Results

The results are plotted in Text-fig. 1. Serum testosterone concentrations were elevated from 40 until 60 days post coitum and averaged 0.47 ± 0.31 (s.d.) ng/ml, excluding the single high value at 58 days p.c. From 60 until 100 days post coitum serum testosterone concentrations were significantly lower (0.15 ± 0.08 ng/ml, P < 0.05) than those between 40 and 60 days p.c. In the perinatal period serum testosterone concentrations rose, the highest concentrations occurring in the 2nd and 3rd week after birth (1.30 ± 0.38 ng/ml) and declining thereafter (P < 0.05). The serum testosterone concentrations then remained relatively low (0.47 ± 0.40 ng/ml), with only occasional high values, until the 18th week of age when they rose significantly (1.77 ± 0.96 ng/ml; P < 0.05).
Discussion

In the fetal pig the Leydig cells show a high degree of differentiation between 35 and 40 days post coitum (Moon & Hardy, 1973). In this same period testicular testosterone concentrations are elevated (Raeside & Sigman, 1975) and testosterone secretion by testicular tissue in vitro is enhanced (Stewart & Raeside, 1976). In the 7th week post coitum the testis displays a morphological regression (Moon & Hardy, 1973) and a diminished biochemical activity (Raeside & Sigman, 1975; Stewart & Raeside, 1976). Our results show that serum testosterone concentrations remain elevated until the end of the 2nd month p.c. and decline thereafter, probably in parallel with the morphological and biochemical changes, although these are not extensively documented. Although we obtained some high values about 57 days p.c. the peak in serum testosterone concentrations reported by Meusy-Dessolle (1974) could not be detected.

The principal function of the elevated concentrations of serum testosterone in the second month after conception is most likely to be the differentiation of the male genital tract and the sexual differentiation of centres in the central nervous system (Dörner, 1976). Morphological differentiation of the genital apparatus in the pig takes place between 28 and 55 days p.c. (Koning, 1942; Marrable, 1971). Brain sex differentiation occurs in many species, and probably also in the pig, just after the morphological differentiation of the genital apparatus (Dörner, 1976).

Gubernacular development and subsequent testicular descent usually occur in the pig between 65 and 85 days post coitum, and the low serum testosterone levels and the reduced steroid-histochemical activity of the testis (van Straaten & Wensing, 1978) at this time support the postulate that testicular descent is not dependent on increased concentrations of testosterone in the peripheral circulation (Wensing, 1973).

The rise of serum testosterone concentrations in the perinatal period until the 2nd and 3rd week after birth and the subsequent decline are comparable with the changes known to occur with age in the testosterone concentration (Booth, 1975; Segal & Raeside, 1975), the steroid-histochemical activity (Wrobel et al., 1973; van Straaten & Wensing, 1978) and the morphological differentiation (Dierichs, Wrobel & Schilling, 1973; van Straaten & Wensing, 1977) of the testis. All these changes are probably related directly to serum LH concentrations (Colenbrander, Kruip, Dieleman & Wensing, 1977) which show a comparable pattern but are earlier.

The significance of the increased testicular activity during the perinatal period remains obscure. The decline of serum testosterone concentrations after the 3rd post-natal week may be due to the maturation of the hypothalamic-hypophysial-gonadal feedback system. That this feedback system does not operate in the immediate neonatal period is indicated by the observations that neonatal serum testosterone concentrations rise in parallel with the increasing serum LH concentrations (Colenbrander et al., 1977). Castration in the pig at 8 weeks of age causes an increase in serum LH concentrations (Colenbrander et al., 1977). It might therefore be concluded that the hypothalamic-hypophysial-gonadal feedback system starts to operate before 8 weeks after birth, and most probably in the 2nd or 3rd week of life.

The decrease and generally low concentrations of serum testosterone after the 3rd post-natal week parallel the changes in testicular testosterone concentrations reported by Elsaesser, König & Smidt (1972). The increase of serum testosterone after 18 weeks of age is correlated with increased morphological differentiation and steroid histochemical activity in the testis (Wrobel et al., 1973; van Straaten & Wensing, 1978), and appears at an earlier stage than that reported by Meusy-Dessolle (1975). Testicular testosterone concentrations remain low (Ruokonen & Vihko, 1974; Booth, 1975), but there is probably enhanced testosterone production because the percentage of Leydig cells in the whole testis is diminished as the tubular component increases (van Straaten & Wensing, 1977).

We thank Mrs H. B. W. Clotscher-Rooseboom, Mrs C. M. J. E. van Rossum-Kök and Mr H. G. Biering for technical assistance.
