Periovulatory gonadotrophin and ovarian steroid patterns in sheep of breeds with differing fecundity

Laboratoire de Physiologie de la Reproduction, Centre de Recherches de Tours, Nouzilly 37380, France

Summary. Plasma hormone concentrations before and during luteolysis (induced by injection of a prostaglandin analogue on Day 10 or 11 of the cycle), during the period of preovulatory follicle growth and ovulation were examined in sheep with known differences in ovulation rate (Romanov, Préalpes, Romanov × Préalpes cross, Ile de France). The number of CL at the time of treatment and the ovulation rate in the ensuing cycle were established by endoscopy. Plasma concentrations of FSH, LH, progesterone and total oestrogen were measured by radioimmunoassays in the 3 days before PG injection, then hourly for the 24 h after PG injection and 2-hourly for a further period up to about 100 h after PG injection. The onset and duration of oestrus were also recorded.

Although breed differences were observed for many of the features studied, only the intervals between oestrus and the LH peak and between PG injection and the LH peak were significantly correlated with ovulation rate.

Introduction

It is well established that gonadotrophins are responsible for follicular growth and ovulation in most mammals, including sheep, although it is not yet known whether quantitative differences in plasma gonadotrophins and ovarian steroid hormones in sheep are related to the number of ovulations. In sheep, and in other domestic livestock, the question is important in research programmes that evaluate the use of hormone measurements as an aid to identification and selection of animals with high genetic merit for fertility and fecundity. A difficulty that arises in such studies, however, is the choice of when to make the hormone measurements, how frequently and for how long. In the present study we examined LH, FSH, progesterone and oestrogen concentrations in sheep genetically different with respect to ovulation numbers during the period from the end of the luteal phase of one oestrous cycle until the completion of the ovulation that follows. Part of this work has been presented in abstract form (Bindon, Blanc, Pelletier, Terqui & Thimonier, 1975).

Previous studies with similar objectives include those of Thimonier & Pelletier (1971) and Land, Pelletier, Thimonier & Mauléon (1973), although these involved other breeds of sheep and examined LH only.

Materials and Methods

The ewes were taken from a flock comprising 8 Romanov, 12 Préalpes du Sud (Préalpes), 12 Ile de France and 20 Romanov × Préalpes crosses. The Romanov breed has a mean litter size of 2.5–2.6 (Desvignes, 1971) while the Préalpes and Ile de France have litter sizes of 1.5 and

* Present address: CSIRO, Division of Animal Production, Private Mail Bag, Armidale, New South Wales 2350, Australia.
1.3 respectively (Desvignes & Thimonier, 1971). They were 2–4 years old at the time of the investigation in October–November 1974 and were kept entirely indoors at Tours, France (47° 30'N) on a diet providing daily intakes of 400 g dehydrated lucerne, 200 g dehydrated maize and cereal straw ad libitum. The animals were the progeny of at least 4 sires of each breed.

At the time of the experiment daylength was approximately 8 h 45 min and the temperature in the animal house 5–15°C.

**Experimental procedure**

The experimental plan is outlined in Text-fig. 1. For ease of blood sampling the ovarian cycles of the ewes were synchronized by treatment with progestagen-impregnated pessaries (40 mg Cronolone: SC 9880, G. D. Searle, France). Of the 52 ewes treated with pessaries 34 were still closely synchronized by the time of intramuscular injection with 100 μg I.C.I. 80,996 (a prostaglandin analogue) on 26 November, i.e. Day 10–5 or 11 of a normal oestrous cycle (Day 0 = day of oestrus).

All blood samples were taken by jugular venepuncture into evacuated tubes. Oestrus was detected by using entire, aproned rams during a 20-min period every 2 h. Blood sampling and detection of oestrus occupied 20 min every 2 h. The animals showed no obvious signs of stress during the experiment, and their feed intake remained unchanged throughout. Ovulation number was assessed by endoscopy during barbiturate anaesthesia (Thimonier & Mauléon, 1969) 6 days after oestrus.

This experimental design therefore permitted comparison of the following items in the 4 breeds of sheep known to be different in fecundity: (1) the luteolytic response to the prostaglandin (PG) analogue injected at a precise stage of the luteal phase; (2) the interval from PG injection to onset of oestrus and duration of oestrus; (3) the number of ovulations before and after PG analogue treatment; (4) the plasma hormone concentrations of LH, FSH, progesterone and total oestrogens in the 3 days before and the next few days after PG analogue injection, i.e. the period when preovulatory follicle growth and ovulation occur.

**Hormone estimations**

Within 30 min of each blood sampling, plasma was separated by centrifugation at 4°C and then stored at −15°C until assay. Unless otherwise indicated all samples were assayed for a particular hormone in a single assay to eliminate inter-assay variation.
LH. Duplicate 100 μl plasma samples were assayed for LH by the specific double-antibody method of Pelletier, Kann, Dolais & Rosselin (1968). Sensitivity of this assay was 0.5 ng/ml plasma and the within-assay precision 7%. The samples were assayed in two batches: the first included all samples up to the point of onset of oestrus and the second included those from the onset of oestrus until some hours after the end of oestrus. The results are expressed as ng LH-M3/ml plasma (LH-M3 = 1.8 × the potency of NIH-LH-S1). The LH discharge was assumed to commence when LH concentration exceeded 6 ng/ml of plasma. The magnitude of the preovulatory LH peak was calculated as the area under the curve of the discharge and expressed as ng LH/ml plasma/h as if all the LH release into the blood occurred at a constant rate.

FSH. Plasma FSH levels were measured by an homologous radioimmunoassay using CNRS-FSH-P26 (biologically equivalent to 40 mg NIH-FSH-S1/mg in the Steelman–Pohley (1953) bioassay) as the reference standard and as the radiiodinated hormone. After absorption of the antiserum by purified ovine LH, cross-reactions with ovine prolactin, GH, ACTH, TSH or LH were all less than 0.2%. Assay sensitivity was 0.4 ng/ml plasma and within-assay variation 5%. Dilution of plasma from a castrated ram, pituitary extracts or various grade purified ovine FSH preparations gave results parallel to those of the reference standard. The results are expressed as ng FSH-P26/ml plasma.

Progesterone. The radioimmunoassay used was that described by Palmer & Jousset (1975). The antiserum was raised in rabbits to progesterone-11-hemisuccinate–BSA. The between- and within assay coefficients of variation for the assay were 5.4% and 3.3% respectively. Progesterone determinations, on duplicate 0.5 ml plasma extract samples, were obtained only for Samples 1–50, since these were expected to encompass the period of luteolysis.

Total oestrogens. The method used for total oestrogen was the radioimmunoassay described by Terqui, Delouis, Thimonier & Ortavant (1975) and by Palmer & Terqui (1977); it included an enzymic hydrolysis and employed an antiserum raised in rabbits to oestrone conjugated to BSA at position 17. The cross-reactions were 100% with oestrone, 75% with 16-ceto-oestradiol-17β, 65% with 16α-hydroxyoestrone and 39% with oestradiol-17β. The results are expressed as pg total oestrogen/ml plasma. Intra-assay variability was 7% for 2 ng/ml (n = 10) and the inter-assay variability 17% for 3.8 ng/ml (n = 20).

Statistical analyses

For each animal the following observations were included in the analysis: time (h) from PG analogue injection to onset of oestrus; duration (h) of oestrus; ovulation rate (no. of CL) in cycle before PG analogue injection; ovulation rate (no. of CL) after PG analogue injection; mean LH level in plasma samples taken −24, −48, and −72 h before PG analogue injection; baseline value of LH, i.e. mean of all plasma samples outside the region of the LH peak; total LH release during the LH peak (ng/ml/h); peak value of LH recorded; interval (h) from onset of oestrus to the LH peak; interval (h) from PG analogue injection to LH peak; mean FSH in samples −24, −48 and −72 h before PG analogue injection; mean FSH from time of PG analogue injection until onset of oestrus; mean FSH during oestrus; mean FSH from end of oestrus to last plasma sample (i.e. approximately 24 h after end of oestrus); maximum value of FSH recorded; mean progesterone level in Samples 1–12, before PG analogue injection; time (h) from PG analogue injection to the point where a 50% reduction in the progesterone level in Samples 1–12 was achieved; time (h) from PG analogue injection until completion of luteolysis, taken as the point where in two consecutive samples progesterone levels were <0.5 ng/ml; mean total oestrogen in plasma samples taken −15 and −18 h before PG analogue injection; mean total oestrogen level from time of PG analogue injection to onset of oestrus; mean total oestrogen level during oestrus; mean total oestrogen level during the 24 h after the end of oestrus; time from PG analogue injection to the total oestrogen peak value; maximum total oestrogen value recorded after PG analogue injection and before onset of oestrus; maximum
total oestrogen value recorded during oestrus. For each of these items the mean values and their standard errors for sheep of each breed were computed and subjected to an analysis of variance for assessment of the significance of the breed effects. The pooled (i.e. across the 4 breeds) correlation coefficients for all possible combinations of the above responses were produced.

Results

Oestrus and ovulation after PG analogue injection

As shown in Table 1, Romanov ewes experienced oestrus significantly earlier than those of the other 3 breeds. There were also substantial differences in the duration of oestrus with the breeds ranking in the order Romanov > Romanov × Préalpes > Préalpes > Ile de France.

* One animal was eliminated from this group for measurements other than ovulation rate before PG; see text.
† Groups with different superscripts differ significantly.

Ovulation rate was also ranked in this order, before the PG analogue injection and in the next cycle, but in none of the breeds did the ovulation rate differ at the two times.

The mean lengths of the oestrous cycle were 16-4, 16-4, 16-2 and 16-6 days for Romanov, Préalpes, Romanov × Préalpes and Ile de France breeds and the cycle following PG analogue injection was of normal length. Abnormal responses were noted in 2 ewes. One Romanov ewe remained in oestrus for 8 days and one Romanov × Préalpes ewe failed to experience complete luteolysis: data for both ewes were eliminated from part of the analyses.

Ovulation in sheep of low and high fecundity breeds

Text-fig. 2. Mean plasma progesterone concentrations in Romanov (●●●●●), Préalpes (■■■■■), Romanov × Préalpes cross (○——○), and Ile de France (+——+) ewes before and after PG analogue injection. The duration of oestrus for each breed is shown by the horizontal bars.

Plasma progesterone

Mean progesterone concentrations before and during luteolysis for the 4 breeds are shown in Text-fig. 2. The data are further analysed in Table 2. It is clear that the Romanov ewes had significantly higher progesterone values than those of the other breeds, and although the early rate of luteolysis was faster in this breed, the time required for complete luteolysis was significantly longer for these animals.

Plasma total oestrogen

The 7 separate estimates of total oestrogen activity for the 4 breeds are summarized in Table 3 and the sequential pattern for each breed shown in Text-fig. 3. During most periods of the experiment the Ile de France and Romanov × Préalpes ewes had higher concentrations than the other ewes. Soon after PG analogue injection there was an abrupt discharge of total oestrogen. The only other consistent feature was the peak value of total oestrogen recorded during oestrus: there was a tendency for this to coincide with the LH peak, although this was not consistent for
Significance

Romanov and Préalpes breed differences* breed de differences de general, sheep in France investigators, results, summarized in Table 4, show that only minor breed differences were observed. The Romanov and Ile de France ewes tended to have higher FSH levels before the PG analogue injection and before, during and after oestrus. The ewes of lowest fecundity (Ile de France) had, in general, the highest overall FSH concentrations, although these were not always significantly higher than in the Romanovs. Most ewes (28 out of 32 examined) showed an increase in FSH concentration that coincided with the LH discharge, although this was not as clear-cut as reported elsewhere (see Hay & Moor, 1975). Most animals also showed an elevation of FSH values in the period after the end of oestrus, corresponding to Days 1 and 2 of the subsequent cycle. The actual levels of FSH reported here (i.e. 2–25 ng/ml) are lower than those described by other investigators, perhaps because of the different FSH standard used.

Significance of breed differences‡

- N.S.

* Mean of 12 samples on Days 8, 9 and 10.
† All values except those of the LH peak.
‡ Groups with different superscripts differ significantly.

Plasma LH levels

There were no significant breed differences in LH levels during Days 8–10 of the cycle (i.e. before PG injection) nor in the overall baseline value (Table 5). The total LH released and the peak level recorded during the preovulatory peak were also similar for the 4 breeds. There were, however, substantial breed differences in the timing of the LH peak. Although Romanov ewes showed oestrus earlier than the other groups (Table 1) there were still significant breed differences when the interval examined was that from PG analogue injection to LH peak: the ewes with the higher ovulation rates had a longer interval between injection and LH release than the Ile de France ewes.

A small discharge of LH occurred in all animals 7–8 h after PG analogue injection. The discharge, expressed as a percentage increase of the level of LH before injection, was larger for the Romanov and the Romanov × Préalpes ewes (75 and 129% respectively) than for the

Préalpes and Ile de France ewes (68 and 60% respectively). The biological significance of the discharge is unknown.

Correlation between preovulatory measurements and ovulation rate

In Table 6 the correlation coefficients for ovulation rate following PG analogue injection and a selection of preovulatory measurements are presented. The largest of the coefficients barely reaches statistical significance.

Discussion

The main purpose of this investigation was to study the quantitative relationships between plasma hormone concentrations and ovulation rate in sheep. It is not possible to assume that the hormone patterns reported here are necessarily the same as in the normal oestrous cycle, because luteolysis was induced several days earlier than would occur in a normal cycle. Following luteolysis, however, the ewes of the four breeds were shown to have a mean ovulation rate not significantly different from that of the previous cycle. To this extent, the expected genetic differences were preserved in this experimental design. Observations before and after PG analogue injection confirm the higher ovulation rate of Romanov ewes (Table 1) and demonstrate that the ovulation rate of the Romanov × Préalpes ewes falls mid-way between that of the parent breeds. This supports the conclusion of Land et al. (1973) that the genetic differences in ovulation rate of these sheep are largely additive.

Our results confirm the luteolytic properties of the PG analogue (I.C.I. 80,996: 16-aryloxy-prostaglandin) which have been described by Challis, Foster, Furr, Robinson & Thorburn (1975) and Acritopoulou, Haresign, Foster & Lamming (1977). The additional points of interest in the present experiment were the earlier onset of oestrus in the Romanov ewes and the significantly longer time required for complete luteolysis in these animals. In ewes of the other 3 breeds the rate of luteolysis was similar to that described by other investigators (e.g. Baird & Scaramuzzi, 1975). It is not clear whether this difference is solely because most Romanov ewes had 3 CL at the time of PG analogue injection or whether it reflects other characteristics of the Romanov breed. Larger doses of PG might accelerate luteolysis in sheep with 3 CL. These points may have practical significance in synchronization programmes, although it is not known whether time of ovulation was different in the Romanov ewes.

Despite the longer luteolysis the Romanov ewes showed oestrus earlier than did the other ewes, although the Romanovs had the lowest total oestrogen levels before and after injection of the PG analogue. The longer duration of oestrus in the Romanov ewes confirms the work of Land et al. (1973) on this breed and supports the general view (Dunlop & Tallis, 1964; Land, 1970; Hanrahan & Quirke, 1975) that duration of oestrus is positively correlated with litter size and ovulation rate. In the present study (see Table 6) duration of oestrus showed a small, positive correlation \( r = +0.23 \) with ovulation rate. The duration of oestrus was not, however, correlated with total oestrogen values. The average total oestrogen level during oestrus and the peak value recorded during oestrus were in fact negatively correlated \( r = -0.32 \) and \(-0.30\) respectively with duration of oestrus. It must be assumed, then, that ewes like the Romanov which show oestrus earlier, stay in oestrus longer and have the highest ovulation rate, are more sensitive to circulating oestrogens.

An important feature of the present experiment was the investigation of the relationship between FSH levels and ovulation rate. If quantitative differences in FSH are responsible for differences in the number of follicles that enter the preovulatory growth phase, produce oestrogen and ovulate, then the present study should have confirmed it. The measurements of FSH during the period that followed the PG analogue injection should have coincided with the
period when terminal follicle growth and ovulation itself were in progress. It is clear from Table 4
that there were small breed differences in the FSH levels but these were not in the direction that
might be expected. The breed with lowest ovulation rate (Ile de France) had the highest FSH
levels. It therefore seems that if FSH levels are related to ovulation rate the present results
indicate that the moment of determination of ovulation rate is not located in the 4–5 days before
oestrus.

There are no other reports of attempts to relate FSH levels to breed differences in fecundity
of adult sheep, although Findlay & Bindon (1976) have shown that ewe lambs from Merinos of
high fecundity have higher FSH levels than those from Merinos with low fecundity.

Breed differences were not evident in the LH measurements shown in Table 5, and similar
results were reported by Thimonier & Pelletier (1971) and Land et al. (1973). These authors also
showed that the interval between onset of oestrus and LH discharge was longer in Romanov
ewes (Land et al., 1973) or in ewes within the breed with the highest ovulation rate (Thimonier &
Pelletier, 1971). The present experiment substantiates this point and although the interval
between PG analogue injection and oestrus is shorter in Romanov ewes, the interval between the
injection and the LH peak is longer than in the Ile de France ewes.

It has been suggested (Hay & Moor, 1975) that the LH discharge terminates preovulatory
follicle activity, or at least the ability to secrete oestradiol. If this is true, the high fecundity
animals like the Romanov would have a longer period available for preovulatory follicular
development before this is brought to a halt by the LH peak. It is yet to be established, of course,
whether in the normal oestrous cycle the interval between luteolysis and LH discharge is
influenced by breed effects as it is after PG-induced luteolysis. Both the higher progesterone
concentrations and extended luteolysis in the Romanov breed may play a significant regulatory
role in the ovulation rate of the next cycle.

Based on the present investigation it must be concluded that apart from progesterone there
are no consistent, positive associations between peripheral plasma levels of ovarian steroids or
plasma gonadotrophins and the fecundity ranking of the 4 breeds studied. For example, although
ewes of the Romanov breed regularly shed about twice as many eggs as do Ile de France ewes,
they have slightly lower FSH, similar LH and significantly less total oestrogen concentrations
during the period when terminal follicle growth and ovulation take place. It is also possible that
the ovaries of high fecundity sheep contain more follicles, are more sensitive to a fixed quantity
of gonadotrophin, or that ovarian incorporation of gonadotrophin is higher in these animals. It
must also be conceded that hormonal regulation of ovulation rate may occur at times in the
oestrous cycle other than those studied here.

This experiment was made possible by the approval of Monsieur R. Ortavant, former
Director of the laboratory, and by the generous assistance of many staff members at Nouzilly.
Special thanks are due to Monsieur C. Cornu and staff for maintenance of the experimental
animals, and Ms M. Cheers and Mrs E. Shutler of CSIRO, Australia, for assistance in data
analysis. Part of this work has been supported by D.G.R.S.T. (grant no. 73-7-1886). The FSH
(CNRS-FSH-P26) was kindly supplied by Dr M. Jutisz (Gif/Yvette, France).
