Summary. Uptake and metabolism of [3H]testosterone, mainly to 5α-dihydrotestosterone (5α-DHT) and 5α-androstanediol were higher in the caput than in the cauda epididymidis in vitro. The metabolites represented 57, 49 and 47% of the total radioactivity in the caput, corpus and cauda epididymidis, respectively; subcellular distributions of the metabolites in each segment showed 67% of total radioactivity in cytosol and 18% in the nuclei. In both fractions, the amount of 5α-DHT was greater than that of androstanediol while the reverse was true for the mitochondria and microsomes.

The distribution of 5α-reductase activity in subcellular fractions was similar to that of the microsomal marker enzyme NADPH: cytochrome C reductase, whilst 3α-hydroxysteroid dehydrogenase was found mainly in the cytosol. Maximal 5α-reductase activity was at pH 5.3, apparent K_m values in the microsomal and nuclear fractions were 1.65 ± 0.7 and 1.75 ± 0.36 × 10^-6 M respectively, and the V_max in these preparations was 5.28 ± 1.19 and 3.1 ± 0.52 pmol/mg protein/min, respectively. The activity of 5α-reductase was inhibited by Zn^{2+}, Cu^{2+}, Ba^{2+} and Cd^{2+} and by epitestosterone, progesterone and 4-androstene-3-one-17β-carboxylic acid.

Introduction

Evidence gathered from several different laboratory species has shown that the maintenance of normal morphology and function of the epididymis are androgen dependent (Hamilton, 1975) and that circulating testosterone is necessary for spermatozoa to acquire and retain their fertilizing capacity (Orgebin-Crist, Danzo & Davies, 1975). These androgen-dependent events are initiated following the uptake of testosterone by the epididymis, its conversion to the more active hormone 5α-dihydrotestosterone (5α-DHT) and its binding to specific receptors (Gloyna & Wilson, 1969; Blaquier, 1971; Hansson, Ritzén, French & Nayfèh, 1975).

This general scheme of androgen action has been found for the rhesus monkey epididymis (Blaquier, 1974; de Larminat & Blaquier, 1978), but there is little information regarding the epididymis in man. In the present study we have investigated the uptake and metabolism of androgens by the human epididymis in vitro and partly characterized the enzyme NADPH:Δ⁴-5α-reductase (EC 1.3.1.22) (5α-reductase) which catalyses the transformation of testosterone into 5α-DHT.
Materials and Methods

The following radioactive steroids were purchased from New England Nuclear (Boston, Massachusetts, U.S.A.): [1,2-3H]testosterone (sp. act. 41 Ci/mmol); [1,2-3H]dihydrotestosterone (sp. act. 50-6 Ci/mmol) and [4-14C]dihydrotestosterone (sp. act. 57 mCi/mmol). [4-14C]5α-Androstan-3α,17β-diol was prepared as described previously (Monsalve & Blaquier, 1977). Non-radioactive steroids were obtained from Steraloids Inc. (Wilton, New Hampshire, U.S.A.) and all other chemicals and reagents were of analytical grade.

Human epididymides were obtained from 8 patients undergoing orchidectomy as treatment for metastatic prostate carcinoma. The patients selected for this study had not received any hormonal or radiation therapy during the 6 months preceding the operation. The average age was 65-9 years (range 55-76 years). After removal, the testes and epididymides were immediately placed on ice and transported to the laboratory where all subsequent procedures were performed at 4°C. After removal of the tunica albuginea, the testis and the adherent fat were separated from each epididymis, which was then divided into three segments corresponding to the caput, corpus and cauda epididymidis (corresponding to segments 1b–2b; 3–3b and 3c–4c, respectively, illustrated in Text-fig. 1 by Bedford, Calvin & Cooper, 1973).

Androgen uptake and metabolism studies. The tissues were minced with scissors and aliquots (300 mg) were incubated for 1 h at 33°C in 2 ml Krebs–Ringer–phosphate (Umbreit, Burris & Stauffert, 1957) glucose buffer, pH 7.4, containing 1-8 × 10^6 d.p.m. [3H]testosterone (10^-8 M). The preparation was extensively washed with buffer and homogenized in 4 volumes of 20 mM-Tris, pH 7.4 containing 3 mM-CaCl2 and 0-15 M-sucrose. Subcellular fractions were prepared by differential centrifugation as described previously (Monsalve & Blaquier, 1977).

After addition to tracer amounts of [14C]5α-DHT and [14C]androstanediol, the fractions were extracted with 2 volumes of ethyl acetate. The ethyl acetate was separated from the aqueous phase and evaporated. The sediment was dissolved in chloroform: methanol (2:1 v/v) and aliquots of this mixture were chromatographed on silica gel plates (Eastman Kodak, New York, U.S.A.) with chloroform: either (4:1 v/v) as the eluant and carrier androstenedione and testosterone. The plates were visualized under u.v. light and the radioactive steroids were located. The corresponding zones were scraped into columns and eluted with methanol. After evaporation, the sediment was dissolved in a toluene-based scintillation fluid and the radioactivity was counted.

Assay for 5α-reductase. Aliquots of the subcellular fractions were incubated for different periods of time at 33°C in the presence of 1 mm-NADPH and [3H]testosterone at concentrations ranging from 10^-7 to 5 × 10^-6 M and 5α-reductase (EC 1.3.1.22) activity was measured as described by Monsalve & Blaquier (1977). The activity of 3α-hydroxysteroid dehydrogenase (EC 1.1.1.50) was determined in the same way but with [3H]5α-dihydrotestosterone as the substrate.

Values are mean ± s.e.m. for 3 experiments, performed with tissues from 3 different patients. Results were normalized for 1 g tissue wet weight and metabolism data are expressed as % of the total radioactivity in each segment.
After incubation, testosterone, 5α-dihydrotestosterone and androstanediol were extracted and separated as described above; 5α-reductase activity was expressed as the sum total of 5α-DHT and androstanediol formed at 33°C per mg protein and per unit of time.

For the determination of \( K_m \) and \( V_{\text{max}} \) values the subcellular fractions were incubated in triplicate for 20 min at 33°C with 0-1, 0-2, 0-5, 1, 2 and 5 μM of [3H]testosterone and the results were represented as Lineweaver-Burke plots. Protein concentrations were determined by the method of Lowry, Rosebrough, Farr & Randall (1951). The activity of NADPH cytochrome C reductase (EC 1.6.2.4) was estimated as described by Avruch & Hoelzl (1971).

**Results**

**Uptake and metabolism**

After incubation of the minced epididymides with [3H]testosterone, 33% of the radioactivity was retained within the tissue. The uptake of [3H]testosterone was highest in the caput epididymidis and lower in the other segments (Table 1). A large proportion of the testosterone was, however, converted to metabolites which had the chromatographic mobility of 5α-DHT and 5α-androstanediol (Monsalve & Blaquier, 1977). These represented 57, 49 and 47% of the radioactivity in the caput, corpus and cauda segments respectively. In all cases 5α-DHT was more abundant than androstanediol. The androstanediol fraction consisted of a mixture of the 3α- and 3β-isomers which were not separated by the chromatography system used in this study. There was proportionally more 5α-DHT in the caput epididymidis (41%) than in the corpus and cauda (28 and 29% respectively).

The subcellular distribution of the incorporated steroids was uniform throughout the organ. Most of the radioactivity was associated with the cytosol (67%) and nuclei (18%), the mitochondria and microsomes containing 8-1 and 6-3% of the radioactivity, respectively.

The extent to which [3H]testosterone was metabolized differed in the 3 segments (Text-fig. 1). Caput cytosol and nuclei contained more 5α-reduced steroids (73 and 66%, respectively)

**Text-fig. 1.** Results for 3 epididymides showing the subcellular localization of [3H]testosterone and its metabolites (5α-androstanediol and 5α-dihydrotestosterone) in the caput, corpus and cauda segments. Aliquots (300 mg) of the tissues were incubated with \( 10^{-8} \) M [3H]testosterone for 1 h at 33°C. The results were normalized to 1 g tissue wet weight and expressed as the percentage of total radioactivity found in each fraction. The subcellular fractions were cytosol (C), nuclei (N), mitochondria (M) and microsomes (μ). The microsome fractions from the corpus segment were accidentally lost.
than did the corresponding fractions from the corpus (50 and 39%) or cauda (59 and 24%). The proportion of 5α-DHT in the 5α-reduced fraction was also variable throughout the epididymis, representing 76 and 50% for caput cytosol and nuclei, 44 and 69% in the corpus and 55 and 82% for these fractions in the cauda epididymidis. While 5α-DHT was, in general, the predominant 5α-reduced metabolite in the nuclei and cytosol, androstanediol was always more abundant in the mitochondrial and microsomal fractions.

**Characteristics of 5α-reductase**

As shown by Text-figs 2(a) and 2(b) the distribution of 5α-reductase activity was very similar to that of NADPH:cytochrome C reductase. Since the latter is a microsomal marker enzyme, 5α-reductase is probably also associated with the microsomal membranes. The activity of 3-hydroxysteroid dehydrogenase was located mainly in the soluble fraction (Text-fig. 2c). The activity of the microsomal 5α-reductase was maximal at pH 5·3 (Text-fig. 3).

**Text-fig. 2.** Subcellular distribution of (a) 5α-reductase, (b) NADPH:cytochrome C reductase and (c) 3-hydroxysteroid dehydrogenase activities in the human epididymis. Results (n = 2) are mean values of data from 4 experiments and are expressed as the relative specific activity (% total activity/% total protein content) plotted against the cumulative value for the % protein content.

**Text-fig. 3.** Effect of pH on the 5α-reductase activity of the microsomal fraction from the human epididymis. Aliquots of the microsomal fraction were incubated with 1 μM-[3H]testosterone and 1 mM-NADPH for 30 min at 33°C. Buffers were calibrated at intervals of 0·25 units of pH; 20 mM-acetate was used for pH 3–5, 20 mM-phosphate for pH 5–7, and 20 mM-Tris for pH 7–8·75.
When different bivalent cations were tested, at a concentration of 1 mM in the medium, Zn$^{2+}$ had the greatest inhibitory effect (46 ± 3.22% inhibition), with Cu$^{2+}$ (32 ± 2.24%), Ba$^{2+}$ (25 ± 1.75%) and Cd$^{2+}$ (21 ± 1.47%) being less effective. Ca$^{2+}$ (105 ± 7.35%) had no effect. Addition of 17α-hydroxy-4-androsten-3-one, progesterone and 4-androsten-3-one,17β-carboxylic acid, at concentrations of 1 µM, resulted in 66 ± 4.62, 64 ± 4.48 and 55 ± 3.85% inhibition respectively. The addition of 5α-DHT or androstanediol (10$^{-6}$ M) to the incubation medium did not modify 5α-reductase activity.

The values (mean ± s.e.m. for 3 observations) obtained for $V_{\text{max}}$ and the apparent $K_{m}$ were 3.1 ± 0.52 pmol/mg protein/min and 1.75 ± 0.36 × 10$^{-6}$ M respectively for the nuclear preparation, and 5.28 ± 1.19 pmol/mg protein/min and 1.65 ± 0.70 × 10$^{-6}$ M respectively for the microsomal preparation.

**Discussion**

The results of this study show that the human epididymis is capable of the uptake and retention of androgens. The comparison of the segmental distribution of radioactivity suggests that androgens are concentrated in the caput region, while the analysis of the subcellular distribution indicates that these steroids are found mostly in the cytosol and nuclei.

Testosterone is extensively converted to its 5α-reduced metabolites, as shown by Gloyna & Wilson (1969) and Sulcovà & Starka (1973) and the caput segment was more active in this regard than the corpus and cauda. The ratio of 5α-DHT:androstanediol varied in each segment, being highest in the caput. This was also the case when this ratio was determined in subcellular fractions from each segment. Caput cytosol and nuclei contained a higher proportion of 5α-DHT than did the same fractions from other segments. The extent of the reduction of testosterone suggests that this is a physiologically important mechanism for androgen action in the human epididymis. Purvis, Calandra, Sander & Hansson (1978) measured the endogenous androgen concentration in human testis and epididymis and found that the testosterone:5α-DHT ratio was highly variable: 106 in the testis and only 3.6 in the epididymis. The change was due not only to a decrease in the testosterone content in the epididymis, but also to the fact that this organ contained almost twice as much 5α-DHT as did the testis, thus suggesting the local production of this steroid. Purvis et al. (1978) also determined the testosterone:5α-DHT ratio in a semipurified epididymal fraction, enriched in cytoplasmic receptor; the value obtained was 0.6, showing a relative 6-fold increase in the concentration of 5α-DHT. Taken together, these results strongly suggest that the epididymis in man utilizes androgens in a manner similar to that shown for rats in which 5α-DHT interacts with epididymal intracellular receptors and thus mediates the effects of testosterone for the maintenance of epididymal function (Orgebin-Crist et al., 1975).

Our present results, showing that most of the 5α-reductase activity is associated with membranes of the endoplasmic reticulum in the human epididymis, agree with previous reports on the subcellular localization of this enzyme in the rat (Monsalve & Blaquier, 1977) and monkey (de Larminat & Blaquier, 1978) epididymis, as well as in other androgen target tissues (Chamberlain, Jagarineck & Ofner, 1966; Voigt, Fernández & Hsia, 1970; Moore & Wilson, 1972).

Further similarity between the 5α-reductase in the human epididymis and that in the rat (Monsalve & Blaquier, 1977) and monkey (de Larminat & Blaquier, 1978) is shown by the acidic pH value for optimum activity, the correspondence of $K_{m}$ values and the decreases in enzyme activity caused by the presence of bivalent cations or steroids.
