Central Veterinary Laboratory, Ministry of Agriculture, Fisheries & Food, New Haw, Weybridge, Surrey, KT15 3NB, U.K.

Summary. Plasma progesterone and gonadotrophin levels were studied in anoestrous ewes treated during June or July with a subcutaneous progesterone implant and/or an injection of oestradiol or PMSG. Of 32 ewes treated with progesterone during July, 9 showed a gonadotrophin surge after removal of the implant, and 10 ewes showed oestrous behaviour during the following 4 days. Six ewes conceived at this induced oestrus. Progesterone treatment during June was much less effective, with only 2 of 19 treated ewes showing a gonadotrophin surge and oestrous behaviour. Administration of PMSG at the time of implant removal in the June experiment was followed by a gonadotrophin surge and oestrous behaviour in 18 of 19 ewes, and 15 ewes conceived at the induced oestrus. An injection of PMSG, without progesterone pretreatment, stimulated a gonadotrophin surge and ovulation, but did not result in oestrous behaviour. The treatments employed appeared to initiate cyclic ovarian activity in the July experiment, but not in the June experiment.

Introduction

Seasonally anoestrous ewes can be induced to show a fertile oestrus by a period of treatment with progesterone or a synthetic progestagen followed by an injection of PMSG (Gordon, 1971; Boland & Gordon, 1973). Saba, Cunningham, Symons & Millar (1975) reported that treatment of ewes with progesterone during July–August induced ovulation, but there was a low incidence of overt oestrus, and Boland & Gordon (1973) concluded that, in the absence of PMSG, progestagen treatments resulted in only a limited ovulatory response with a high proportion of ewes having ‘silent’ heats. It has also been reported that fertility is improved by the administration of oestradiol to anoestrous ewes at the start of progesterone treatment (Hulet & Stormshak, 1972). In the present paper we present data on plasma hormone levels, reproductive behaviour and fertility in anoestrous ewes treated during July and June of 2 consecutive years with subcutaneous progesterone implants and/or oestradiol or PMSG injections.

Materials and Methods

Progesterone implants

Solid Silastic implants (10 cm long × 0.5 cm diam) containing 0, 13 or 20% (w/w) progesterone were prepared according to the method of Mauer et al. (1972) using Dow Corning 382 Medical Grade Elastomer as described previously (Cunningham, Saba & Millar, 1975). The 13 and 20% progesterone implants contained ~260 and ~460 mg progesterone, respectively.
Experimental animals and treatments

Experiment 1. Fifty (50) Cheviot × Border Leicester ewes aged 18 months, which would normally be expected to begin cycles in October, were housed in 4 indoor pens at the beginning of July. The ewes were divided into 3 groups treated as shown in Table 1. The implants were inserted subcutaneously on 11 July using the technique described earlier (Symons, Cunningham, Saba & Millar, 1974) and after 11 days were removed from half of the ewes at 09:00 h (subgroups A) and from the remainder at 21:00 h (subgroups B). At the time of implant insertion, ewes in Groups 1 and 3 received an intramuscular injection of a fine suspension of 500 µg oestradiol-17β in 2 ml 0-9% (w/v) NaCl. Group-2 ewes were injected with 2 ml 0-9% (w/v) NaCl.

Experiment 2. The following year, 49 of the Cheviot Cross ewes and an additional 7 North Country × Suffolk Cross halfbreed ewes of about the same age were housed at the beginning of May. Treatment (as shown in Table 1) commenced on 2 June, and the implants were removed 14 days later, half of the ewes having the implants removed at 17:30 h (subgroups A) and the remainder at 05:30 h (subgroups B). Immediately following removal of the implant, each ewe in Groups 5 and 7 received an intramuscular injection of 500 i.u. PMSG in 1·3 ml 0-5% phenol (Folligon: Intervet), and ewes in Groups 4 and 6 received 1·3 ml solvent alone (0-5% phenol).

Blood sampling

Samples of jugular blood were collected in heparinized Vacutainers before insertion of the implants and at 1, 5 and 11 days (Exp. 1) or 1, 7 and 14 days after implantation (Exp. 2). Following removal of the implants, samples were collected every 3 h for 72 h (Exp. 1) or every 4 h for 96 h (Exp. 2) and at 1–3 day intervals thereafter until 3 weeks after implant removal. Blood plasma was stored at −20°C until required for hormone assays.

Radioimmunoassay of hormones

Plasma FSH and LH were determined by the polystyrene tube radioimmunoassays previously described (Cunningham & Hebert, 1973; Symons, Cunningham & Saba, 1974). Sensitivities of the assays were 0·4 ng NIH-FSH-S4/tube and 2·5 ng NIH-LH-S17/tube, and inter- and intra-assay coefficients of variation were respectively 15 and 5% for FSH and 12 and 8% for LH. Plasma progesterone was estimated in Exp. 1 by a modification (Symons, 1973) of the dextran-coated charcoal radioimmunoassay for oestrogens described by Challis, Heap & Illingworth (1971) and in Exp. 2 by a charcoal-gelatin disc radioimmunoassay (Saba, 1976).
Progesterone and PMSG treatment of anoestrous ewes

Antiserum S49-6 (obtained from Dr G. E. Abraham) was used for both experiments; this was raised in sheep against 11-desoxycortisol-21-hemisuccinate–HSA and its specificity has been described (Abraham, Swerdloff, Tulchinsky & Odell, 1971). The assays were sensitive to 25 pg progesterone/tube and inter- and intra-assay coefficients of variation were 16 and 6% respectively.

Reproductive behaviour

Four rams fitted with marking harnesses were run with the ewes for 5 weeks from 1 week after insertion of the implants. Each ram was penned with 12–14 ewes and rams were changed between pens periodically. Ewes were examined daily for signs of marking by the rams and those having a definite marking were removed from the rams to a separate pen.

In Exp. 2, mating by the rams was confirmed by taking samples of vaginal mucus from marked ewes and examining them under the microscope for the presence of spermatozoa.

Results

In Exp. 1, 7 ewes from Group 2 and 5 from Group 3 developed abscesses and fibrous tissue around the implants, presumably a reaction to the local high concentration of progesterone. Absorption of progesterone from the implants in these ewes, as evidenced by loss of weight of the implants and plasma progesterone levels during the period of implantation, was reduced compared to that in ewes which did not develop abscesses. Results from these 12 ewes have therefore not been included.

One ewe from Group 6A and 1 from Group 7B lost their implants before Day 14 after implant insertion and results from these 2 ewes have also been excluded from consideration.

Effects of implants on plasma progesterone levels

Mean (±s.e.m.) plasma progesterone levels during the period of implantation for the 2 experiments are summarized in Table 2. Data for Groups 2 and 3 (Exp. 1) have been pooled, since there was no significant difference in mean plasma progesterone concentration between these 2 groups at any of the times studied. In both experiments insertion of progesterone implants was followed by a significant rise in plasma progesterone concentration at 24 h (P < 0-001), and there was a significant fall in the level 12 h after implant removal (P < 0-001). By contrast, ewes treated with a blank implant showed little change in mean plasma progesterone level after insertion or removal of the implants.

Table 2. Mean (±s.e.m.) plasma progesterone concentrations (ng/ml) in anoestrous ewes treated for 11 or 14 days with subcutaneous implants containing 0, 13 or 20% (w/w) progesterone

* Significantly different from the preceding value (P < 0.001).
At the end of the period of implantation, mean (±s.e.m.) loss of weight of the implants was 86·4 ± 1·6 mg for those containing 20% progesterone (n = 32) and 87·2 ± 2·0 mg for those containing 13% progesterone (n = 38), whereas mean loss of weight of blank implants in the 2 experiments was 2·3 ± 1·0 mg (Exp. 1, n = 6) and 4·8 ± 1·0 mg (Exp. 2, n = 16). These data suggest that the implants released approximately 84 mg progesterone over 11 days in Exp. 1 and 82 mg progesterone over 14 days in Exp. 2.

**Experiment 1**

Changes in plasma hormone levels following implant removal

The time of day at which the implant was removed (09:00 h and 21:00 h for subgroups A and B) had no effect on the pattern of hormonal responses following implant removal, and the data for subgroups A and B have therefore been combined.

**Gonadotrophins.** At the time of implant removal, mean (±s.e.m.) plasma LH level in 6 ewes treated with a blank implant (5·6 ± 0·6 ng/ml) was not significantly different from that in ewes of Groups 2 (6·4 ± 0·7 ng/ml, N = 7) and 3 (4·9 ± 0·3 ng/ml, N = 25) treated with a progesterone implant. However, mean plasma FSH level was significantly higher (P < 0·01) in Group-3 ewes (53·8 ± 3·6 ng/ml) treated with oestradiol and progesterone than in ewes of Groups 1 (33·8 ± 4·1 ng/ml) and 2 (31·4 ± 5·3 ng/ml).

Data on plasma gonadotrophin surges following implant removal are summarized in Table 3. Nine ewes treated with a 20% progesterone implant (Groups 2 and 3) showed a gonadotrophin

‡ Not sampled.
surge during the 72 h following implant removal, with peak plasma LH concentrations ranging from 33 to 156 ng/ml. All ewes showing an LH surge exhibited a simultaneous rise in plasma FSH concentration to peak values ranging from 170 to 330 ng/ml. None of the ewes treated with a blank implant exhibited a gonadotrophin surge during this period (Table 3).

**Progesterone.** All 9 ewes in which a gonadotrophin surge was observed showed a pattern of rising plasma progesterone concentration to values ≥1 ng/ml by 11 days after implant removal. In addition, 1 ewe in Group 3 which had not exhibited a gonadotrophin surge showed a similar plasma progesterone pattern and presumably had a gonadotrophin surge later than 72 h. Mean plasma progesterone levels for these 10 ewes during the 18 days following implant removal are shown in Text-fig. 1.

Plasma progesterone levels were not elevated in the remaining 28 ewes, and on Day 11 after implant removal mean (±s.e.m.) plasma progesterone concentrations were 0.19 ± 0.03 ng/ml (blank implant, N = 6) and 0.19 ± 0.04 ng/ml (progesterone implant, N = 22).

![Text-fig. 1](image)

**Text-fig. 1.** Mean (±s.e.m.) plasma progesterone concentrations for ewes ovulating in Exp. 1 (—O—) and in Exp. 2; Groups 4 (—●—), 5 (—▲—) and 7 (⋯⋯⋯⋯⋯⋯).

**Reproductive behaviour**

No ewes were marked by the rams during the period that the implants were in position. Ten ewes, including 8 of those which showed a gonadotrophin surge, were served by the rams during the 3 days following implant removal and 6 conceived to this service (see Table 3). The remaining 4 ewes returned to oestrus after an interval of 12–23 days, and 2 conceived.

An additional 13 progesterone-treated ewes were marked by the rams during the period 11–29 days after implant removal, and 3 conceived. Five returned to oestrus after a further interval of 15–18 days and 4 conceived. Two control ewes were in oestrus at about 2 weeks after removal of the blank implant, and returned to oestrus at Day 32. A third control ewe showed a fertile oestrus 29 days after implant removal.
Experiment 2
Changes in plasma hormone levels following implant removal

As with Exp. 1, the time of day at which the implant was removed did not appear to influence the pattern of hormonal responses and the data for subgroups A and B have been combined.

Gonadotrophins. Mean (±s.e.m.) plasma gonadotrophin levels at the time of implant removal in 38 ewes treated with a progesterone implant (2.5 ± 0.5 ng LH/ml; 18.2 ± 1.3 ng FSH/ml) were similar to those in 16 ewes receiving a blank implant (2.4 ± 0.6 ng LH/ml; 21.9 ± 1.5 ng FSH/ml).

Data on plasma gonadotrophin surges following implant removal are summarized in Table 3. The values of the gonadotrophin surges exhibited by ewes in Groups 5 and 7 during the first 48 h following implant removal reached 28–175 ng LH/ml and 92–305 ng FSH/ml. The remaining Group-7 ewe showed small elevations of plasma LH (10 ng/ml) and FSH (42 ng/ml) at 39 h. The gonadotrophin surge occurred significantly earlier (P < 0.001) in the ewes of Group 5 than in those of Group 7, but mean peak heights were similar for the two groups (Table 3). In ewes not treated with PMSG (Groups 4 and 6), plasma gonadotrophins remained at basal levels throughout this period.

One Group-5 ewe showed a second plasma gonadotrophin surge at about 80 h following implant removal. A late surge in plasma gonadotrophins, occurring at 75–95 h, was also observed in 3 Group-4 ewes and in 2 Group-6 ewes. Peak gonadotrophin levels during these later surges ranged from 20 to 75 ng LH/ml and 50 to 123 ng FSH/ml.

Progesterone. Plasma progesterone levels remained below 1 ng/ml during the 21 days following implant removal in all of the ewes which had not exhibited a gonadotrophin surge, whereas elevated levels were observed in all of the Group-7 ewes, 7 of the 10 Group-5 ewes and the 5 ewes in Groups 4 and 6 which had shown a gonadotrophin surge. Mean (±s.e.m.) plasma progesterone level for those ewes in Groups 4, 5 and 7 exhibiting elevated levels are shown in Text-fig. 4. Of the 2 Group-6 ewes having a gonadotrophin surge, one showed a slow rise in plasma progesterone concentration to 0.7 ng/ml on Days 9 and 11, followed by a fall and a subsequent rise to 1.25 ng/ml on Day 18. The other showed a more rapid rise to 1.95 ng/ml at 84 days and 2.75 ng/ml at 11 days—a pattern intermediate between that of Groups 5 and 7.

The plasma progesterone profile for Group-5 ewes (blank implant + PMSG) was similar to that found in Exp. 1, whereas mean plasma progesterone concentration in Group-7 ewes (progesterone implant + PMSG) rose more rapidly and reached a higher level than that observed in ewes of other groups. The 3 control ewes (Group 4) which exhibited gonadotrophin surges showed a delayed slow rise in plasma progesterone concentration, a pattern quite different from that shown by the treated groups of ewes (see Text-fig. 1).

Reproductive behaviour

No ewes were served by the rams during the period that the implants were in position, or during the period 5–28 days after implant removal.

Data on oestrous behaviour and conception during the first 4 days following implant removal are given in Table 3. The 2 Group-6 ewes which showed a plasma gonadotrophin surge were served at about the time of peak gonadotrophin levels, and one conceived. None of the ewes in Groups 4 and 5 showed oestrous behaviour despite the fact that 13 had exhibited a gonadotrophin surge and 10 showed a subsequent increase in plasma progesterone concentration.

Although the time of day at which the implant was removed did not affect the timing of hormonal responses, it appeared to influence the time of occurrence of oestrous behaviour in Group-7 ewes. The mean (±s.e.m.) interval from gonadotrophin peak to mating was shorter for Group-7B ewes (3.3 ± 2.3 h, N = 9) than for Group-7A ewes (14.2 ± 4.6 h, N = 10).
to July-August of extent, present pituitary consistent both reducts...surges...basal gonadotrophin was...ewes...plasma...duration there...However,...progesterone...it...in...ewes treated with blank implants were also higher in Exp. 1 than in Exp. 2. However, within each experiment, plasma LH concentrations at the time of implant removal were similar for ewes treated with a blank or progesterone implant, but plasma FSH level was significantly elevated in ewes treated with oestradiol followed by progesterone (Group 3). We cannot explain the reason for this rise in FSH concentration, but neither oestradiol (Group 1) nor progesterone alone (Groups 2, 6 and 7) produced such an elevation.

Some of the control ewes treated with blank implants also exhibited signs of ovarian activity. It seems unlikely that the oestrous behaviour shown by control ewes in Exp. 1 was stimulated by the single injection of oestradiol given at the time of implant insertion, but it is possible that, in both experiments, the responses of the control ewes were triggered by the presence of rams. It is known that the onset of the breeding season can be advanced by the sudden introduction of rams to anoestrous ewes but, in British breeds of sheep, this advancement seldom exceeds 6 weeks (Lindsay, 1976). However, Bellinger & Mendel (1974) found that the introduction of rams to anoestrous Suffolk and Hampshire ewes during the months of April to June provoked a degree of ovarian activity associated, in some cases, with behavioural oestrus and, occasionally, a fertile mating.

The results for the treated groups of ewes extend previous observations on hormonal changes and the induction of oestrus in anoestrous ewes treated with progesterone implants. Progesterone treatment alone appears to be more effective in provoking gonadotrophin surges in anoestrous ewes as the natural breeding season is approached. Thus the percentage of ewes showing such surges was 11% in early June (Group 6), 28% in mid-July (Groups 2 and 3) and 90% in July–August (Saba et al., 1975). This progressive change in the effectiveness of progesterone is consistent with the known seasonal variation in the response of anoestrous ewes to progesterone treatment (Robinson, 1971). It may reflect an increase in the sensitivity of the hypothalamo–pituitary system to endogenous oestrogen with the approach of the breeding season, since Land, Wheeler & Carr (1976) have found that ovariectomized ewes show a reduced response to the stimulatory effects of exogenous oestrogen on LH release during anoestrus. Furthermore, in agreement with the work of others (Renfro & Dutt, 1970; Gordon, 1975), the results of the present experiments suggest that progesterone treatment during July is more effective in initiating cyclic activity than is treatment during June, which would be consistent with a reduction in the refractoriness of the hypothalamo–pituitary system during late anoestrus. However, it cannot be ruled out that the responses of the ewes treated in July might, to some extent, have been a consequence of the higher plasma progesterone levels achieved in Exp. 1.
An important difference between the present results and those reported earlier (Saba et al., 1975) is that ewes which showed gonadotrophin surges following progesterone treatment during June and July also exhibited oestrous behaviour, whereas the majority of ewes treated during the later stages of anoestrus (July-August) had 'silent' ovulations. Robinson (1959) has emphasized the importance of progesterone before oestrogen in inducing cyclic activity in spayed ewes, and the low incidence of oestrous behaviour reported by Saba et al. (1975) may therefore have been a consequence of the relatively low plasma progesterone levels achieved during implantation.

The importance of progesterone priming as a prerequisite for oestrous behaviour is also evident when the responses of ewes treated with PMSG or PMSG plus progesterone are compared. Treatment with PMSG alone was very effective in provoking a gonadotrophin surge at 27 h after injection, but none of the ewes showed oestrous behaviour although elevated plasma progesterone levels during the period 9–20 days after the PMSG injection suggested that the ewes had ovulated and formed active corpora lutea. In marked contrast, ewes treated with PMSG after a period of elevated plasma progesterone concentration (Group 7), showed a gonadotrophin surge at 33 h after the PMSG injection which was associated with a fertile oestrus. The 5 h delay in the occurrence of the gonadotrophin surge in progesterone + PMSG-treated ewes compared with those receiving PMSG alone may reflect the time required for release of the pituitary from progesterone inhibition. An even longer delay was observed in ewes showing a gonadotrophin surge following treatment with progesterone implants in Exp. 1. The higher plasma progesterone levels at the time of implant removal might account for this delay since, in Exp. 1, plasma progesterone concentration had not reached basal levels by 12 h after implant removal (see Text-fig. 1) and the pituitary would therefore have been under the influence of elevated progesterone levels for a longer period.

Hulet & Stormshak (1972) found that fertility was higher in anoestrous ewes treated with 2 mg oestradiol-17β at the time of insertion of a progesterone implant, but we found no evidence of such an improved response. On the contrary, the proportion of ewes exhibiting a gonadotrophin surge and oestrous behaviour following removal of the implant was lower for Group 3 than for Group 2, although this difference was not statistically significant because of the small number of ewes in Group 2. The lack of a beneficial effect of oestradiol in Exp. 1 may have been a consequence of the smaller dose of oestradiol administered (0·5 mg), and the effects of higher doses should perhaps be investigated.

A remarkable feature of the ewes treated with progesterone + PMSG in the present experiments was the rapidity with which plasma progesterone levels increased following treatment (see Text-fig. 1), and this may have contributed to the high level of fertility observed for the Group-7 ewes. The early rise in plasma progesterone concentration may have resulted from the rapid formation of an actively secreting corpus luteum, or perhaps from the formation of several corpora lutea as a consequence of multiple ovulations stimulated by the PMSG injection. Boland & Gordon (1973) found that the administration of 500 i.u. PMSG to anoestrous ewes following progestagen treatment increased the number of multiple ovulations, and the higher lambing rate shown by Group 7 (1·9 lambs/ewe lambing) compared with Groups 2 and 3 (1·2 lambs/ewe lambing) would be consistent with such an explanation. Nevertheless, treatment with PMSG alone (Group 5) did not result in an early rise in plasma progesterone level.

It has been suggested that the interval between the gonadotrophin surge and the occurrence of oestrous behaviour may have some bearing on fertility at an induced oestrus (Echternkamp & Lunstra, 1978), and in an earlier paper (Cunningham, Saba & Millar, 1977) we reported that the time of day at which a progesterone implant was removed from ewes treated in late anoestrus affected the interval from removal to the gonadotrophin surge. No such effect was observed when ewes were treated with progesterone + PMSG in mid-anoestrus, as in the present experiments, although time of day of removal of the implant did have an effect on the interval from the gonadotrophin surge to the occurrence of oestrous behaviour. Thus, although there was
a 12 h difference between Groups 7A and 7B in the times of removal of the implants (17:30 h and 05:30 h), and of the occurrence of the gonadotrophin surge, mean times of mating for Groups 7A and 7B differed by only 2 h. These observations suggest that there may be diurnal variations in the effectiveness of the centres responsible for oestrous behaviour. However, time of day of removal of the implant had no significant influence on fertility at the induced oestrus.

We thank the National Institute of Arthritis, Metabolism and Digestive Diseases, U.S.A., for the gift of pituitary hormone preparations used in the radioimmunoassays; Miss C. N. Hebert for the statistical analyses; and Mr P. Harrington, Mr R. Jackson, Mrs A. M. Kerry, Mrs V. Mackintosh, Mr T. C. Martin and Mr P. M. Raby for valuable technical assistance.
