Summary. Oocytes were removed from follicles 5–30 mm in diameter. The germinal vesicle was present in 69.6\% (23/33) of the oocytes at the start of culture, but after 20–24 and 40 h 70.5\% (12/17) and 68.2\% (43/63) of the oocytes were in metaphase I and metaphase II with first polar body extruded, respectively.

Introduction

Pincus & Enzmann (1935) were the first to observe that rabbit oocytes resume meiosis when cultured outside the follicle. Since that time oocyte maturation has been investigated in many mammals, including farm animals (for review, see Thibault, 1977). However, there is limited knowledge of oocyte maturation in horses and the present study of horse oocytes \textit{in vitro} was therefore undertaken.

Materials and Methods

Oocytes were aspirated from antral follicles of different sizes (5–30 mm) in the ovaries of slaughtered mares. The ovaries of 8–12 mares were usually taken at each collection. Oocytes in the follicular fluid were transported to the laboratory in a container at 30°C. There they were removed from the follicular fluid under a stereomicroscope and only those (80) with a compact cumulus were used. The oocytes were washed 3 times in medium and cultured in 0.1 ml medium under paraffin oil in 5\% CO₂ in air at 37.5°C. The composition of medium was that described by Pavlok & McLaren (1972) and modified by Motlik & Fulka (1974).

Two culture intervals, 20–24 h and 40 h, were chosen, and 33 oocytes served as a control of nuclear stage at the start of culture. The cumulus cells were removed by gently sucking the oocytes through a narrow pipette and the oocytes were mounted, fixed in acetic alcohol (1:3 v/v), stained with orcein and evaluated under a phase-contrast microscope.

Results

Approximately 30 oocytes were obtained in each collection, i.e. 3–5 oocytes per mare. Most control oocytes (Table 1) were at the germinal vesicle stage with a clearly visible nucleolus, finely granulated nucleoplasm and distinct nuclear membrane. Chromatin, intensively stained in a horseshoe pattern, was detected at the periphery of the nucleolus (Pl. 1, Fig. 1), or as an orcein-positive material distributed in the nucleoplasm.
After culture for 20–24 or 40 h, more oocytes were in metaphase I (Pl. 1, Fig. 2) and metaphase II (Pl. 1, Figs 3 and 4), respectively. Oocytes for which the stage of development was difficult to identify were classed as abnormal.

Discussion

The results presented here show that horse oocytes need a relatively long period for their nuclear maturation in vitro. In most mammalian species the sequence of chromosomal changes continues more rapidly, but pig (Motlik, 1972), human (Jagiello, Ducayen, Miller, Graffeo & Fang, 1975) and sheep (Quirke & Gordon, 1971) oocytes also have a longer maturation. The use of more oocytes for detailed studies would be desirable but in horses this possibility is limited by the low number of antral follicles in the ovaries, particularly in the autumn when these experiments were carried out and the sexual activity of mares is very low (Bielański, 1972; Driancourt, 1979).

The relatively large numbers of oocytes classified as abnormal are probably due to the derivation of the oocytes from atretic follicles, in spite of the selection before culture and the use of oocytes with cumulus cells. McGaughey, Montgomery & Richter (1979) showed that oocytes from pig follicles at different stages of atresia resume but do not complete meiosis.

Further studies of horse oocyte maturation should also consider the controversy about development in the preovulatory follicles; Hamilton & Day (1945) claimed that dictyate oocytes are normally ovulated and that maturation is completed in the oviduct, while Van Niekerk & Gerneke (1966) consider that metaphase II occurs shortly before ovulation. According to Webel, Franklin, Harland & Dziuk (1977) both observations are correct. These authors found freshly ovulated oocytes at metaphase II in pony mares and also oocytes which had not yet completed maturation. These oocytes were examined 42–52 h after hCG injection. It means that the time necessary for maturation in vivo and in vitro, observed in our experiments, is very similar.

J. Fulka thanks Professor W. Bielański and Dr M. Tischner who made it possible to carry out this study and provided valuable discussion. The investigation was supported by grant No. MR 2.10 from the Agriculture Academy in Wrocław, Poland.
