Differentiation of decidual cells in mouse endometrial cell cultures

Reproductive Immunology Research Group, Department of Pathology, The Medical School, University of Bristol, Bristol BS8 1TD, U.K.

Summary. Mouse uterine cells were obtained by trypsinization of uteri at timed intervals after the induction of a decidual reaction by intraluminal instillation of arachis oil on Day 4 of normal pregnancy. Cells were also obtained from ovariectomized mouse uteri, some of which had received a progesterone–oestadiol sequence to sensitize the uterus to a decidual stimulus. The differentiation of decidual cells was followed in cultures of these cells. The morphology of the cells obtained after 6 days in culture was dependent upon the seeding density employed. At low seeding density (plating densities of 75–100 cells/mm²) no net increase in cell number was observed, but large mononucleated stellate cells were present, with cytoplasmic and nuclear areas increased by 4-fold. At higher seeding densities (plating densities of up to 709 cells/mm²), a prolongation of cell survival and the appearance of substantial numbers of binucleated cells were observed. However, both cell types were characterized by the accumulation of filamentous material in the cytoplasm. Even at optimal seeding density the life-span of the decidualized cells could not be prolonged beyond 9 days. Uterine cells from hormone-treated ovariectomized animals underwent similar transformations but those from untreated ovariectomized mice gave only isolated islets of epithelial cells and scattered fibroblast-like cells in culture. These observations suggest that discrepancies in previous reports of in-vitro decidualization of rat uterine cells result from differences in the seeding densities employed.

Introduction

Endometrial stromal cells of the rat and mouse uterus in response to the implanting blastocyst or certain artificial stimuli undergo proliferation and differentiation resulting in the formation of the decidual cells of the decidua of pregnancy or the deciduoma of pseudopregnancy (De Feo, 1967; Finn, 1971; Psychoyos, 1973). The process, termed decidualization or the decidual cell reaction, has been studied in vivo at the morphological and, more recently, at the biochemical level (Denari, Germino & Rosner, 1976; Ledford, Rankin, Markwald & Baggett, 1976; Rankin, Ledford & Baggett, 1977; Ledford et al., 1978; Moulton & Blaha, 1978; Moulton, 1979; Serra, Ledford & Baggett, 1979). The appearance of bi-, tri- and multinucleated cells, polyploid nuclear populations (Krehbiel, 1937; Leroy, Bogaert, Van Hoeck & Delcroix, 1974) and of abundant thin cytoplasmic filaments (Tachi, Tachi & Lindner, 1970) are constant features of early decidualization. Many of the biochemical parameters investigated in this system may reflect cellular growth, but more recent studies suggest that more specific alterations of protein synthesis are associated with the system (Yoshinaga, 1972, 1974; Glasser & Clark, 1975; Bell, 1979a, b, c). The decidua and deciduoma have a limited life-span and the tissue regresses after approximately 2 weeks (Velardo, Dawson, Olsen & Hisaw, 1953; De Feo, 1967).
In spite of these investigations, however, the mechanisms involved in the development and regression of decidual tissue have not been determined. Progress in this area may be facilitated by the development of in-vitro systems of decidual cell differentiation. Decidualization in vitro has been reported for endometrial stem cells from hormone-treated ovariectomized rats (Sananes, Weiller, Baulieu & Le Goascogne, 1978) and from pseudopregnant rats treated intraluminally with pyrathiazine hydrochloride (Vladimirsky, Chen, Amsterdam, Zor & Lindner, 1977). In these reports endometrial cells were hormonally sensitized in vivo prior to culture, and although evidence for decidual cell differentiation in these cultures was presented, major differences in cell morphology were apparent. In the present study we report the establishment of an in-vitro system demonstrating decidual differentiation of mouse endometrial cells and provide a possible explanation for the discrepancies in the previous reports.

Materials and Methods

Animals

The inbred mouse strains CBA/Ca and A were used. Cyclic 3-month-old females were paired with males of proven fertility and the morning on which a copulatory plug was found was designated Day 1 of pregnancy. On Day 4 between 12:00 and 15:00 h these animals were injected intraluminally with 10 µl arachis oil (Hopkin & Williams, Chadwell Heath, Essex, U.K.) per uterine horn, to induce deciduoma formation. Other groups of 3-month-old females were ovariectomized under ether anaesthesia 14 days before experimental treatment. One group of animals received oestradiol daily for 3 consecutive days and after a rest period of 3 days received oestradiol (10 ng) and progesterone (1 mg) daily for 3 consecutive days, both hormones being administered s.c. in 0.1 ml arachis oil (Ledford et al., 1976). Animals in a second group were treated with progesterone only for 3 consecutive days and those in a third group received no hormones. Hormone-treated animals were injected intraluminally with 10 µl arachis oil 24 h after the final hormone injection. Animals were killed by cervical dislocation at 0, 24 and 48 h after instillation of oil. Some animals were killed 24 h after the final hormone injection without injection of oil. The animals receiving no hormones were killed between 16 and 28 days after ovariectomy.

Cultures

For each culture, uterine horns of 3–4 mice were dissected under sterile conditions, cleared of fat and placed in Dulbecco A and B phosphate-buffered saline (DPBS). They were rinsed three times in 10 ml DPBS and subsequently thoroughly minced with iridectomy scissors. The fragments were resuspended three times in fresh DPBS each time, allowing the pieces of tissue to settle before discarding the supernatant, and 10 ml prewarmed (37°C) 0.1% trypsin solution (Difco Laboratories, P.O. Box 14B, West Molesey, Surrey, U.K.) was then added to the fragments in a conical test tube and agitated by pipetting. The fragments were then incubated for 30 min with continuous magnetic stirring at room temperature. The suspension was again pipetted, then left undisturbed until the largest fragments had sedimented and the supernatant was passed through a fine silk gauze. The filtrate was collected in a Petri dish containing 1 ml RPMI-1640 (Gibco (Europe), Paisley, U.K.) containing L-glutamine (0.3 mg/ml), benzyl penicillin (0.06 mg/ml), and streptomycin sulphate (0.05 mg/ml), supplemented with 10% heat-inactivated fetal calf serum and buffered to pH 7.2 with 2 mg sodium bicarbonate per ml, to inhibit the trypsinization. The filtrate was then transferred to a conical test tube and the cells were pelleted by centrifugation at 500 g for 5 min. The pellet was resuspended in 0.5 ml RPMI-1640 + 4.5 ml 0.83% NH₄Cl and incubated for 10 min at room temperature to lyse any contaminating red blood cells. After centrifugation at 800 g for 5 min the pellet was washed
sequentially with DPBS and RPMI-1640 medium (1:1 v/v) and DPBS, and the cells finally resuspended in RPMI-1640 medium, counted in a haemocytometer and diluted to obtain the appropriate cell concentration. Aliquots of 0.4 ml suspension were added to the wells of leucocyte migration plates (Sterlin, Teddington, Middlesex, U.K.) and incubated at 37°C in a humid atmosphere at 5% CO₂ in air. Fresh medium was used after 24 and 48 h and then twice a week.

**Light and electron microscopy**

Cultures were examined daily with a Wild inverted microscope under phase-contrast optics. At various times plates were rinsed and fixed in absolute alcohol for 45 min and, after drying, stained with diluted Giemsa solution (1:10) for 45 min. Numbers of cells within microscopic fields were measured using a 1-cm square graticule and nuclear diameters of all cells were determined using a 1-cm graticule subdivided into 0.1 mm divisions. Approximate nuclear area (a) was estimated using the formula, \( a = (\pi \cdot d_1 \times d_2)/4 \), in which \( d_1 \) and \( d_2 \) are the largest and smallest diameters of the nucleus respectively (Barlow & Sherman, 1972). Other estimates, such as the number of cells and the incidence of polynucleated cells, were based on examination of at least 4 different culture dishes, derived from at least 3 experiments. Light micrographs were obtained of the stained preparations.

Cultures of mouse uterine cells were processed for electron microscopy after different periods in vitro. Cells were fixed in ice-cold cacodylate-buffered 4% glutaraldehyde, pH 7.2, for 4 h, washed for 16 h at 0–4°C in cacodylate-buffered 0.25 M-sucrose and post-fixed in phosphate-buffered 1% osmium tetroxide. The monolayers were dehydrated in ethanol, incubated for 4 h at 37°C in alcohol: Epon 812 solution (1:1 v/v), and embedded by addition of Epon 812 directly into the culture wells. After hardening of the Epon, the plastic wells were removed by snap-freezing in liquid nitrogen or by trimming. Thin sections were stained with lead tartrate and examined in a Philips EM 300 electron microscope at an accelerating voltage of 89 kV.

**Results**

*Cultures of uterine cells from intact animals*

The number of uterine cells obtained by enzyme digestion increased from 1.5 ± 0.4 × 10⁵ cells per uterus at 0 h, 3.8 ± 0.7 × 10⁵ cells per uterus at 24 h to 6.3 ± 1.3 × 10⁵ cells per uterus at 48 h after intraluminal instillation of arachis oil. The plating efficiency of uterine cells, as determined by seeding 6 plates with 1.0 × 10⁵ cells each and subsequent examination after 24 h, increased from 24 ± 9% at 0 h, 45 ± 14% at 24 h to 95 ± 4% at 48 h after intraluminal instillation of oil. Cells attached to the plates within 12 h of seeding and formed monolayers.

In most cultures two populations of mononucleate cells were observed. The major population consisted of dispersed, flat, spindle-shaped or stellate cells and exhibited great changes in culture (Pl. 1, Figs 1–4). The second population of cells, which occurred in low and variable numbers, were round, approximately 8–10 µm in diameter, and did not appear to undergo alterations during culture (Pl. 1, Figs 1–3). A third population of colony-forming cells was observed, but only rarely, in cultures of cells obtained 0 h after intraluminal instillation of arachis oil into uteri of CBA/Ca animals (Pl. 1, Fig. 5). They were more frequently observed in cultures of cells obtained from strain A females and were identical to the colonies observed in cultures of cells obtained from ovariecetomized females. Subsequent observations refer only to the flat stellate cells.

After 24 h in culture cells obtained at different times after oil instillation appeared morphologically different. Cells obtained at 0 h after oil instillation were homogeneous in
appearance after 24 h in culture, with single oval nuclei of uniform size and little cytoplasmic area (Pl. 1, Fig. 1). Cells obtained 24 h after oil instillation possessed increased cytoplasmic volume and larger oval nuclei (Pl. 1, Fig. 2). For cells obtained 48 h after oil instillation, the increase in cytoplasmic volume was most dramatic; the size of the nuclei was further increased (Pl. 1, Fig. 3) and they were often irregular in shape. Binucleate cells were also observed. It was apparent that these alterations in cells after 24 h in culture reflected changes occurring in vivo after oil instillation.

**Cell density.** Considerable alterations were observed during long-term culture of uterine cells, but these appeared to be dependent upon the original seeding density. As shown in Text-fig. 1, at a seeding density of $0.5 \times 10^5$ (plating density at $24\ h = 75\ cells/mm^2$) cell loss occurred throughout the culture period and very few binucleate cells were observed. The remaining cells, however, grew to a large size (Pl. 1, Fig. 4), and their large single nuclei contained many pleomorphic dense inclusions. At a seeding density of $1.0 \times 10^5$ (plating density at $24\ h = 140\ cells/mm^2$) the cell number remained at a steady state for 3 days before cell loss occurred (Text-fig. 1). An increase in cytoplasmic volume and nuclear area was observed, resulting in a paucity of intercellular space, and binucleated cells also occurred after 3 days (maximum 2.5%). Increasing the seeding density to $1.5 \times 10^5$ (plating density at $24\ h = 215\ cells/mm^2$) resulted in further prolongation of cell survival, cell loss now being observed after 6–9 days of culture and a substantial increase in the number of binucleated cells on the third day (maximum 9%). No net increase in cell number was observed until the seeding density was $5 \times 10^5$ (plating density at 24

Text-fig. 1. Mean ± s.e.m. numbers of total cells (●), necrotic cells (□) and binucleated cells (○) in cultures of mouse uterine cells obtained from 24 h after the intraluminal instillation of arachis oil and seeded at (a) 0.5 × 10⁴, (b) 1.0 × 10⁴, and (c, d) 1.5 × 10⁴ cells/mm². For (d) 10⁻⁷ M-progesterone was added to the culture medium.

h = 709 cells/mm²), when after 48 h of culture several overlapping layers of cells were obtained, making accurate cell counting impossible (Pl. 1, Fig. 6). In the less densely plated zones many binucleate cells were observed. Signs of degeneration appeared after 9 days in culture and, as with all the cultures, complete involution occurred by 14–21 days. Although these data were obtained with uterine cells obtained 24 h after intraluminal instillation of oil a similar relationship was observed with all uterine cells, irrespective of time of collection, and also with cells obtained from animals which received no oil injection.

Electron microscopy. The cultures of uterine cells displayed essentially similar fine structural features throughout the entire period of study. Some cells were binucleated and contained large regular-shaped nuclei with prominent nucleoli (Pl. 2, Fig. 8). Small quantities of condensed chromatin lined the inner nuclear membranes. After 96 h in culture irregularly shaped nuclei characterized by deep cytoplasmic protrusions were frequently observed (Pl. 2, Fig. 10).

Within the cytoplasm large amounts of filamentous material were distributed amongst the cytoplasmic organelles and appeared to be arranged into tracts of filaments running in several planes (Pl. 2, Fig. 9). Mitochondria and numerous free polysomes were the only cytoplasmic organelles observed in these filamentous areas. An identical arrangement of cytoplasmic filaments characterizes mouse decidual tissue in vivo (R. F. Searle, unpublished observations). The cisternae of the well-developed rough endoplasmic reticulum were often dilated and contained an electron-dense homogeneous material (Pl. 2, Fig. 8). Numerous free polysomes were also present in the cytoplasm and flat spiral polysomes were observed attached to the rough endoplasmic reticulum (Pl. 2, Fig. 8). In some cells, the Golgi zones were well developed. After periods of culture in excess of 96 h there was a marked accumulation of small lipid droplets, lysomes and autophagic vacuoles within the cytoplasm.
Nuclear size. To obtain a measure of the incidence and the degree of polyploidy in the cell cultures estimations of nuclear area were made. The nuclear area of cells explanted 0 h after intraluminal instillation of oil increased 4-fold during 6 days of culture (170 ± 10 (s.e.m.) versus 680 ± 40 µm², P < 0.001). As shown in Text-fig. 2, although the range of nuclear area was narrow on Day 3 of culture, after 6 days a wide range of sizes was observed up to 1000–1600 µm². Cells explanted at 24 h possessed a higher mean nuclear area after the first day in culture (290 ± 50 µm²), and achieved a similar maximum size after only 3 days in culture (650 ± 50 µm²; Table 1). However, at the higher seeding density of 5 × 10⁴, which resulted in net growth, a mean nuclear diameter of only 470 ± 30 µm² was observed during culture of cells explanted from uteri 48 h after intraluminal instillation of arachis oil.

Values are mean ± s.e.m. for 200 nuclei.

The number of nucleoli, which stained densely with Giemsa, varied from 1 to 6 per nucleus, and were larger when there were fewer. Nuclei from cells explanted at 0 to 24 h, after 6 days in culture, and at 48 h after 3 days, became multi-lobular and very irregular in shape (Pl. 1, Fig. 7; Pl. 2, Fig. 8).

Effect of hormone supplementation. To determine whether the rate of division or the life-span of decidual cells in culture could be increased, the culture medium was supplemented with approximately physiological concentrations of oestrogen (10⁻⁹ M) and progesterone (10⁻⁷ M), the hormones involved with the induction of the decidual cell reaction and the maintenance of decidual tissue in vivo. Addition of these hormones had no effect upon any of the parameters examined in this study.
Cultures of uterine cells from ovariectomized mice

Uterine cells from ovariectomized animals gave rise to two types of cells in culture, small colonies of epithelial cells and dispersed fibroblast-like cells. The colonies were composed of 10–50 cells forming a continuous ‘crazy-paving’ sheet, and possessed a single nucleus of area 170 ± 8 μm², although an occasional binucleated cell was observed. These colonies were identical to the occasional colony observed in cultures of cells obtained from uteri after the instillation of oil (Pl. 1, Fig. 5). No indications of the changes previously observed were detected in these cultures even after 10 days. The fibroblast-like cells remained unaltered in morphology during culture. Uterine cells from hormone-treated animals, however, underwent morphological changes similar to those in cultures of uterine cells from pregnant uteri.

Discussion

Cells explanted from the uteri of pregnant or hormone-primed ovariectomized mice underwent characteristic morphological transformations in vitro. The type of morphologically distinct cell observed depended upon the seeding density of the uterine cells, but both cell types were considered to represent differentiated decidual cells. The typical decidual cellular characteristics observed included binucleation and polyploidy, accumulation of filamentous material, increased number of lysosomes, development of Golgi apparatus, dilatation of rough-surfaced endoplasmic reticulum and numerous polysomes (Jollie & Bencosme, 1965; Tachi et al., 1970; Ansell, Barlow & McLaren, 1974; Sananes & Le Goascogne, 1976). Nuclei of bizarre shape and lobulated have not been recorded in previous in-vitro studies (Vladimirsky et al., 1977; Sananes et al., 1978), but have been observed in vivo in the pseudopregnant deciduoma-bearing rat (Kleinfeld, Morrow & De Feo, 1976). In both morphological types an increase in the DNA content of the cells may be surmised—at the lower densities, the dramatic increase in the area of the single nucleus which correlates with the degree of ploidy (Barlow & Sherman, 1972), and at the higher densities when binucleation was observed. The former probably arise through endoreduplication (Ansell et al., 1974; Leroy et al., 1974) and the latter through karyokinesis without subsequent cell division (Ansell et al., 1974).

In vivo, decidualization in appropriately hormone-primed animals requires the application of a ‘decidual stimulus’. It is possible that the uteri from the pregnant animals had received a decidual stimulus from unimplanted blastocysts although this would not apply to the hormone-primed ovariectomized animals. As in previous reports, the observation of decidual differentiation in cells explanted from unstimulated uteri indicates that the experimental procedure employed to isolate uterine cells must be equivalent to the decidual stimulus in vivo (Vladimirsky et al., 1977; Sananes et al., 1978). The apparent independence of decidual differentiation in vitro from the presence of progesterone is difficult to explain since maintenance of decidualization in vitro exhibits complete dependence upon the presence of this hormone (Finn, 1971; Psychoyos, 1973; Glasser & Clark, 1975). The inability to maintain cultures beyond 1½ weeks, the maximum development at optimal seeding density being obtained after 6 days reflects the situation in vivo, supporting the concept that decidual regression in vivo is due to the limited life-span of decidual cells.

The only previous reports of decidualization of endometrial and uterine cells in vitro have been from studies of rats, in which markedly different, morphologically distinct cellular types have been obtained. Sananes et al. (1978), using uterine cells from hormonally-primed spayed rats, observed binucleated cells which exhibited no contact inhibition and underwent degeneration after 6 days. Net growth was reported. Vladimirsky et al. (1977) explanted endometrial cells from pseudopregnant rat uteri at timed intervals after the induction of the decidual cell reaction with pyrathiazine, and these developed into populations of dispersed spindle-shaped or stellate cells and colonies of closely packed polygonal cells. A net increase in
the number of cells was only observed within the colonies, which also became bi- and multinucleated. The dispersed cells exhibited a doubling in nuclear area and a substantial increase in cytoplasmic volume. Both these reports considered that the cells were decidual cells on the basis of their polyplody and/or binucleation and accumulation of filamentous material. These apparent discrepancies in cellular morphology could have been due to the different physiological condition of the uterine stem cells. However, a more likely explanation could be related to the different seeding densities employed. Sananes et al. (1978) seeded uterine cells at a density of 1000 cells/mm², which was equivalent to the highest densities used in the present study, when we obtained a similar decidual cell morphology and characteristics. Vladimirska et al. (1977) seeded endometrial cells at a density of 55 cells/mm², equivalent to the lower densities used in the present study, and obtained stellate cells identical to those described here. However, we observed colony-forming cells rather infrequently, and due to their similarity to the colony-forming cells found in cultures of uteri from ovariecetomized mice we consider these to be epithelial cells. Luminal epithelial cells, after being exposed to the hormone regimen necessary for implantation and a decidual stimulus, exhibit 'programmed cell death' (Finn & Porter, 1977). According to the method of induction employed, epithelial cells may escape this mechanism and give rise to viable stem cells.

The ability to obtain reproducible decidual cell differentiation in vitro in the mouse provides the opportunity to investigate a number of outstanding problems associated with decidualization, such as the synthesis of decidual cell specific products (Bell, 1979a, b) and the identity of the Ia-bearing cells in the decidua basalis (Jenkinson & Searle, 1979).

We thank Dr W. D. Billington for stimulating discussions and criticisms, Mrs D. Keane for help in the preparation of the manuscript, and Mr C. Jeal for photographic expertise. The work was supported by grants from The Rockefeller Foundation and the Medical Research Council.
