Examination of different preparations of human placental plasma membrane for the binding of insulin, transferrin and immunoglobulins

M. Davies, J. E. Parry* and R. G. Sutcliffe

Institute of Genetics and *Institute of Virology, Glasgow University, Church Street, Glasgow G11 5JS, U.K.

Summary. Plasma membrane was prepared from human placental tissue by two standard methods. The preparations, termed PVM and PPM, examined by electron microscopy and polyacrylamide gel electrophoresis, were characterized with respect to their binding properties for insulin, transferrin, α2-macroglobulin and the immunoglobulins, IgM and IgG1. By means of sucrose density-gradient centrifugation, it was possible to fractionate the PVM into two distinct fractions. The first fraction, under the conditions used, was heavier (density > 1.080 g·cm⁻³) and was obtained as a pellet. It bound transferrin and IgM and had low specific activities for 5'-nucleotidase and for the binding of IgG1. The lighter fraction (density range 1.048–1.050 g·cm⁻³) had a high specific activity for 5'-nucleotidase and for IgG1 binding. Transferrin and IgM did not bind to this fraction. Insulin bound to both the fractions with comparable levels of specific binding activity, while α2-macroglobulin binding was undetectable. The PPM preparation was found to have binding properties similar to those of the light fraction of PVM.

Introduction

The placenta, the physical barrier between the maternal and fetal circulations, exhibits a wide range of membrane phenomena including the binding of active molecules such as insulin (Posner, 1974; Harrison et al. 1977), transferrin (Balfour & Jones, 1977; Faulk & Galbraith, 1979) and immunoglobulins (Faulk, Jeannet, Creighton & Carbonara, 1974; Matre, Tonder & Endresen, 1975; McNabb, Koh, Dorrington & Painter, 1976). The preparation of membrane fractions from this tissue has been described in the literature (Smith, Brush & Luckett, 1974; Snary, Woods & Crumpton, 1976). The method of Snary et al. (1976) employed a mechanical shearing step of the placental tissue and the resultant membrane preparation could have been derived from several cell types, although the trophoblast was presumably predominant because there was a substantial lack of HLA antigens (Goodfellow, Barnstable, Bodmer, Snary & Crumpton, 1976). In the method of Smith et al. (1974), gentle washing was used to extract placental villous surface membrane, presumed to be the brush-border membrane from the maternal-facing surfaces of the syncytiotrophoblast. The justification of this technique was based on electron microscopic studies, which indicated that the chorionic villous surface was almost entirely free of the microvilli after the washing procedure and that little or no cellular damage was visible.

Since membrane studies reported in the literature have used one of these two methods, we investigated whether the membranes prepared by these different techniques were homogeneous and comparable with regard to their binding characteristics for insulin, transferrin and the immunoglobulins, IgM and IgG1.
Materials and Methods

Placental membrane preparations

Placental villous surface membrane. This preparation (PVM) was produced by the method of Smith et al. (1974). Briefly, a fresh term placenta, from which the cord and membranes had been removed, was cut into small pieces and washed rapidly in ice-cold 0.11 M-calcium chloride followed by ice-cold saline (9 g NaCl/l). The washed tissue was placed in saline and agitated for 30 min at 4°C. The saline was removed and centrifuged at 800 g for 10 min. The supernate was re-centrifuged, first at 10 000 g for 5 min and then at 100 000 g for 30 min. The resulting pellet, of placental villous surface membrane (PVM), was re-suspended using a tight-fitting glass homogenizer, and washed in saline by centrifugation at 100 000 g for 30 min.

Placental plasma membrane. This PPM preparation was prepared by the method of Snary et al. (1976). The placental tissue removed from the membranous sheet of a fresh term placenta, was cut into small pieces and washed in ice-cold 0.15 M-NaCl in 10 mM-Tris–HCl buffer, pH 7.3. The washed pieces were forced through a metal grid by means of a mechanical press, and the resultant filtrate passed through muslin. The filtered material was centrifuged at 4000 g for 15 min and the supernate was re-centrifuged at 20 000 g for 30 min. The pellet was re-suspended in 36% (w/v) (density 1.08 g · cm⁻³) sucrose in 10 mM-Tris–HCl buffer, pH 7.3, overlaid with an equal volume of 25% (w/v) (density 1.041 g · cm⁻³) sucrose and centrifuged at 60 000 g for 16 h in a 10 × 10 titanium rotor in an MSE Superspeed 65 centrifuge. The material at the interface was collected and washed free of the sucrose by centrifugation at 100 000 g for 30 min in 10 mM-Tris–HCl buffer, pH 7.3. The final pellet of placental plasma membrane was re-suspended in buffer using a tight-fitting glass homogenizer.

Membrane characteristics

The two membrane preparations were subjected to a variety of analyses (see below for details). Since the PPM was prepared by means of sucrose density gradient centrifugation, the PVM was treated similarly to yield two membranous fractions, termed the pellet fraction and Fractions 4 + 5, respectively. The relationship of these fractions to PVM and PPM is represented in Text-fig. 1.

Sucrose gradient centrifugation. Membrane preparations in 10 mM-Tris–HCl buffer, pH 7.3, were layered onto a continuous gradient of 10–40% (w/v) (density range 1.028–1.08 g · cm⁻³) sucrose in 10 mM-Tris–HCl buffer, pH 7.3 and centrifuged at 60 000 g for 16 h. Fractions (1 ml) were collected by puncturing the bottom of the centrifuge tubes.

Protein estimation. The protein content of the membrane fractions was estimated by the method of Lowry, Rosebrough, Farr & Randall (1951) using bovine serum albumin (BSA) as the standard.

Albumin profiles. Aliquots of the fractions from the sucrose density gradient centrifugation were placed in wells in a 1% (w/v) agarose gel, containing appropriately diluted sheep antiserum against whole normal human serum. The plates were subjected to electrophoresis at 3 mA and at 4°C overnight, before being washed thoroughly in 100 mM-phosphate buffer, pH 7.4, dried and stained for protein in 0.2% Coomassie Blue. The albumin precipitin peaks were quantitated by estimating the area under the peaks.

Enzyme marker estimation. The 5'-nucleotidase (EC 3.1.3.5) activity in the preparations was assessed by means of a commercially available assay kit (Sigma Chemical Co., St Louis, Missouri, U.S.A.).

Electron microscopy. The membrane preparations were centrifuged at 100 000 g for 30 min, washed in two changes of phosphate-buffered saline (PBS: 0.16 M-NaCl in 5 mM-potassium phosphate, pH 7.5) (5 min each) and fixed for 60 min in 2.5% phosphate-buffered glutaraldehyde at room temperature. The pellet, washed in three changes of PBS, was post-fixed
in 1% phosphate-buffered osmium tetroxide for 60 min. After washing in three changes of PBS, the pellet was dehydrated via a series of graded ethanols, up to 100%. The final change was replaced gradually by Epon (Agar Aids, Cambridge Road, Stanstead, Essex) over 48 h. After two changes of fresh Epon and polymerization for 72 h at 65°C, the resin blocks were sectioned on an LKB Ultratome II. Sections 60–80 nm thick were collected on copper grids, stained with uranyl acetate and lead citrate and examined at 80 kV in a Siemens Elmiskopf 101.

Polyacrylamide gel electrophoresis. Samples of membrane material (see ‘Results’ for details) were subjected to electrophoresis by a method similar to that described by Laemmli (1970). Briefly, slab gels with a polyacrylamide gradient of 4.5–15% were prepared in 0.38 M-Tris–HCl buffer, pH 9.4, containing 1% (w/v) sodium dodecyl sulphate (SDS). The 13–14 cm running gel was overlaid with a spacer gel of 4% polyacrylamide in 0.12 M-Tris–HCl buffer, pH 6.7, containing 1% (w/v) SDS. The membrane samples were solubilized by heating to 100°C for 3 min in a mixture containing, as final concentrations, 4 mg membrane protein/ml, 1.2% (v/v) β-mercaptoethanol, 10% (v/v) glycerol and 3.2% (w/v) SDS. A 40 μl solubilized membrane sample was applied to the gels, which were electrophoresed in 0.056 M-glycine in 0.052 M-Tris–HCl buffer, containing 0.1% (w/v) SDS, for 4–5 h at a constant current of 40 mA per gel. The gels were stained for protein with 0.2% (w/v) Coomassie blue in methanol:glacial acetic acid (5:1, v/v) for 1 h at room temperature. The gels were de-stained in methanol:glacial acetic acid (5:1 v/v) for 1 h and then in 10% (v/v) acetic acid until the background was colourless.

Radiolabelling of proteins. 125I was bound to the proteins by the chloramine T method as described by Hunter & Greenwood (1962) using 250–500 μCi carrier-free Na125I, 5–10 μg protein, 5 μg chloramine T and 12 μg sodium metabisulphite in a volume of 45 μl containing 0.2 M-potassium phosphate. The resultant specific activity of labelling was in the range 5–16 μCi/μg protein. The proteins used for radiolabelling were obtained from a variety of sources. Intact porcine insulin, the insulin A and B chains and human transferrin were obtained from the Sigma

Text-fig. 1. Flow diagram of the relationship between the different placental membrane fractions.
Chemical Co. IgM was prepared by euglobulin precipitation and column chromatography (Heide & Schwick, 1978) from the serum of a patient with a Waldenström's macroglobulinaemia (supplied by Dr D. R. Stanworth, Department of Immunology, University of Birmingham, U.K.). Purified IgG₁, from the serum of a patient with multiple myeloma, was also given by Dr Stanworth. Both immunoglobulin preparations were checked for purity by polyacrylamide gel electrophoresis. The α₂-macroglobulin was purified as described by Sutcliffe, Kukulksa-Langlands, Coggins, Hunter & Gore (1980).

Preparation of Fc fragments from IgG₁. Fc fragments were prepared from IgG₁ by cleavage with mercuripapain (Sigma Chemical Co.) using the method of Porter (1959). The digestion products were separated on DEAE-Sepharose CL6B (Pharmacia, Sweden) using the buffer system of Franklin (1960) and on CM-Sepharose CL6B using the buffer system of Porter (1959). Purity was analysed by approximately 20% polyacrylamide–SDS gradient-gel electrophoresis and on Ouchterlony plates using anti-Fc and anti-Fab antisera (Behring Institute, Hoechst Pharmaceuticals).

Binding assays. These were performed by a method similar to that described by Marshall, Underwood, Voina, Foushee & Van Wyk (1974) and Harrison, Billington, East, Nichols & Clark (1978). Briefly, the reaction mixture consisted of 100 µl of an homogenized membrane suspension (100–400 µg), 200 µl bovine serum albumin (5 mg/ml), 200 µl 0.1 M-phosphate buffer, pH 7.4, and variable quantities of the ¹²⁵I-labelled protein (15–50 ng). The reaction mixture was incubated at 4°C for 20 h and centrifuged at variable speeds from 3000 to 100 000 g for 30 min. The radioactivity associated with the pellet and the supernate was estimated.

Results

Purification of plasma membrane

The two placental membrane samples, PVM and PPM, were examined throughout their preparation for enrichment of the plasma membrane enzyme marker, 5'-nucleotidase. Under the conditions of the assay, the PVM preparation showed a 9- to 12-fold increase in specific activity compared with that in the saline-washed starting material, while the PPM preparation exhibited 7- to 9-fold more activity than in the mechanically-disrupted filtrate. The final membrane samples were examined on 4.5–15% polyacrylamide gradient gel electrophoresis, which revealed that both preparations were heterogeneous mixtures of polypeptides, different from each other and from their respective starting materials (Pl. 1, Fig. 1). Examination of the preparations by electron microscopy showed that both samples were reasonably homogeneous, consisting of characteristic membrane vesicles, with a typical bilayer structure (Pl. 1, Figs 2 and 3; Pl. 2, Figs 4 and 5). The PVM preparation was associated with a large amount of amorphous material (Pl. 2, Figs 4 and 5) which could be part of the fibrinoid layer known to cover the microvilli (Currie & Bagshawe, 1967); the nature of this material is being examined.

The protein profile for PVM (Text-fig. 2) showed a U-shaped distribution, with approximately 30% of the applied protein associated with the pellet and 43% with the lighter fractions (density < 1.04 g · cm⁻³). The 5'-nucleotidase activity (Text-fig. 2) was distributed throughout the gradient with a peak of high specific activity associated with Fractions 4 and 5 (density range 1.048–1.05 g · cm⁻³), which contained only 5.5% of the original PVM protein applied to the gradient. The pellet also showed enzyme activity, but it was of lower specific activity. Application of PPM preparation, obtained from the interface of a 36%/25% discontinuous sucrose gradient, to the continuous gradient (Text-fig. 2) showed distribution throughout the gradient, with approximately 27% of the applied protein associated with the 1.048–1.05 g · cm⁻³ density range which also showed a peak of high specific enzyme activity (Text-fig. 2). The serum albumin profile (Text-fig. 2) revealed that albumin was measurable only in the lighter fractions of PVM and PPM (density < 1.045 g · cm⁻³), although a small amount of
material appeared to be associated with or trapped in the PVM pellet. After preparation of the PVM by this density-gradient centrifugation step, the pellet and the Fractions 4 + 5 with high specific activity for 5'-nucleotidase were examined under the electron microscope. Both fractions contained membranous vesicular material (Pl. 2, Figs 6 and 7) similar in nature to the unfractionated PVM and the PPM preparations. The pelleted fraction was associated with a large amount of amorphous material also seen in the unfractionated PVM preparation. The membrane in Fractions 4 + 5 was cleaner in appearance and was similar to the PPM preparation. Examination of the two fractions on polyacrylamide gels showed that the samples were similar to each other but did differ at certain bands (Pl. 1, Fig. 1). For example, the pellet fraction contained a major protein band with an apparent molecular weight of 35 000, which was absent from the material in Fractions 4 + 5.

**Binding properties of the membrane preparations**

In the initial experiments, insulin, immunoglobulins IgG, transferrin and alpha₂-macroglobulin were labelled with ¹²⁵I and incubated with aliquots of the PVM preparation before sucrose density gradient centrifugation. Fractions were collected and examined for the binding of the various proteins. The membrane binding of insulin was examined using intact insulin...
molecules as well as the separate A and B chains. Intact insulin molecules bound with two peaks of high specific binding activity, one associated with the pellet and heavy fractions, and the other with Fractions 4 + 5 (Text-fig. 3a). There was no detectable binding of the separate A and B chains. IgG₁ bound throughout the gradient, with a peak of high specific binding activity associated with Fractions 4 + 5 (Text-fig. 3b). The binding of IgM, which was much less than that of IgG₁, was associated only with the pellet and the heaviest fractions from the gradient (Text-fig. 3c). There was no apparent binding of α₂-macroglobulin but a small amount of transferrin was associated primarily with the pellet and heaviest fractions (Text-fig. 3d).

For comparative purposes the binding of insulin, IgG₁ and transferrin to the PPM, the unfractionated PVM, and the pellet fraction and Fractions 4 + 5 from a sucrose density gradient of PVM were examined. The amounts of each of the radiolabelled proteins binding to the membranes varied considerably and were affected by the age of the preparation. Freshly prepared membranes showed higher degrees of binding than did samples that had been stored at −20°C. Although absolute binding values were not obtained in this assay, which was not performed under strict saturating conditions, data were compiled from several experiments and ranges are shown in Table 1. The specificity of the binding of the proteins was tested, although non-specific binding had been eliminated by performing the assays in the presence of a large excess of BSA. Unlike intact insulin, the separated insulin A and B chains did not bind to the membranes and the binding of ¹²⁵I-labelled insulin was competitively inhibited in the presence of a large excess of non-radioactive insulin and unaffected in the presence of an excess of IgG₁ (Table 2). Similarly, the membrane binding of IgG₁ was inhibited by an excess of unlabelled IgG₁ or the appropriate Fc fragment, but not by an excess of insulin (Tables 2 and 3). Similarly the binding of transferrin was specific with the majority of the labelled protein being displaced in the presence of an excess of unlabelled transferrin and unaffected by IgG₁ and intact insulin (Table 3).

Effect of variable centrifugal forces on binding characteristics

The binding assays for placental membrane samples, as described in the literature (Marshall et al. 1974; Harrison et al. 1978), involve a period of incubation of the tracer protein with a

membrane source followed by a low-speed centrifugation (3000–6000 \(g\)) to yield results based on the amount of radioactivity associated with the pellet and the supernate obtained. In the present studies, the radiolabelled proteins were incubated with membrane samples under standard conditions (see ‘Materials and Methods’), but the reaction mixtures were subjected to a range of centrifugal forces (3000–100 000 \(g\)), which revealed that the membrane preparations were a mixture of fractions that bound insulin and IgG1 and required different centrifugal forces in order to form into a pellet. The results, summarized in Table 4, show that the PVM (whole preparation) and the pellet fraction from the sucrose density gradients of PVM appeared to bind the insulin and the IgG1 in a similar manner. Hence approximately 85% of these labelled proteins bound by the two preparations could be centrifuged into a pellet with a centrifugal force < 12 000 \(g\) with only 14% being bound to a lighter fraction that required higher centrifugal forces (25 000–100 000 \(g\)) to form into a pellet. However, the other samples examined, PPM and the Fractions 4 + 5 from the sucrose density-gradient separation of PVM, appeared similar to each other, and different from the other two preparations, since approximately 50% of the labelled proteins bound required large centrifugal forces (25 000–100 000 \(g\)) to ensure pellet formation.

* Calculated from the formula: \(A/B \times 100\), where \(A\) is the amount of the protein bound to the membrane pellet over the range of centrifugal force examined and \(B\) is the total amount of protein bound to the membrane pellet over the whole range of centrifugal force, 3000–100 000 \(g\).
Discussion

Electron microscopic studies revealed that the preparations of placental membranes obtained by the methods of Smith et al. (1974) and Snary et al. (1976) were similar at low and high magnifications and showed characteristic membrane vesicles with a bilayer structure. Analysis by SDS polyacrylamide gradient gel electrophoresis revealed a heterogeneous mixture of polypeptides with between 9 and 12 major protein bands in the membrane samples. Carlson, Wada & Sussman (1976) have reported at least 26 major polypeptide bands for a membrane preparation of which 16 were major proteins and 10 glycoproteins. Similarly, Ogbimi, Johnson, Brown & Fox (1979) have reported up to 21 discrete protein bands, with the major proteins ranging in apparent molecular weight from 34 000 to 101 000.

Although the PVM and PPM preparations in the present study exhibited morphological and electrophoretic similarities the binding activities of these two membrane preparations for IgG1 and insulin were considerably different, with the PPM being 3.5–5 times more avid. The reason for this difference was not clear and was probably not due to the use of the gradient centrifugation, since the avidity of PVM was not improved by means of this step (Table 1). The greater binding of the PPM might be related to the fact that the method extracts membrane from both faces of the trophoblast rather than from the maternally-facing surface only. However, the higher binding of IgG1 to PPM (compared with PVM) may argue in favour of an enrichment of a membrane fraction from the microvilli which are expected to be rich in the syncytiotrophoblast Fc receptors. The more gentle extraction method for PVM may produce a subset of microvilli which are dissociated from the placenta in relation to a cycle of microvillous ageing, loss and regeneration.

Sucrose gradient centrifugation, a step in the preparation of PPM, was incorporated into the purification of PVM in an attempt to remove passively adsorbed serum proteins. This procedure was useful because most of the serum albumin was found at the top of the gradient. Moreover, the gradient yielded two regions (the pellet and Fractions 4 + 5) which contain membrane detectable in the electron microscope. To study the protein-binding properties of these fractions, PVM was incubated with radiolabelled proteins (insulin, transferrin and immunoglobulin) before being applied to sucrose gradients. The results showed that both fractions of membrane bound insulin at similar levels and that the binding was specific using competitive inhibition as the criterion. However, the membrane fractions differed to a degree in their other binding properties. Transferrin was found in detectable levels only in the pelleted membrane while the specific binding activity for IgG1 was 10 times greater for the membrane in Fractions 4 + 5 compared with the pelleted fraction. The relative avidity of the non-pelleted membrane of IgG1 seemed to correlate with its high specific activity for 5'-nucleotidase. It may be argued that these quantitative differences are solely due to the quality of the membrane purification and to the quantity of the residual protein. However, this does not account for the findings that insulin binds to both membrane fractions while the transferrin and IgM bind only to the pelleted membrane fraction. Further, the problem of membrane aggregation, although difficult to estimate, was not considered to be significantly affecting the sucrose gradient results because each membrane fraction possessed reproducible characteristics with respect to protein binding and 5'-nucleotidase activity.

It is possible that the relatively greater binding of IgG1 to the lighter fraction of membrane might be due to the Fc receptors in the pellet fraction being saturated with endogenously bound IgG. It is difficult to answer this problem in the light of current knowledge but immunoglobulin light chain bands could not be detected in the SDS–polyacrylamide gel experiments. The lack of detectable antibody protein in the pellet fraction shows that it was not present, complexed to Fc receptors, in quantities sufficient to precipitate antibody-bound membrane as the pelleted membrane fraction, leaving the light fraction to bind the 125I-labelled IgG1.

It therefore seems probable that a separation has been made between two somewhat different
fractions of microvillous membrane. It is highly probable that both fractions come from the microvillous brush border since the method of the initial extraction of PVM is very gentle and contaminating blood and other cells are removed by the early centrifugation steps. Nelson, Smith & Jarrett (1978) have reported that membrane receptors for insulin have a non-uniform distribution on the maternal aspect of the trophoblast, being associated with the distal ends of the microvilli. This is in contrast to the distribution of IgG receptors which are found on the microvillous and inter-microvillous membrane (King, 1977). It is not known whether these histological findings correlate with the heterogeneity reported in the present results. Other factors, such as patterns of ageing of the trophoblast and its associated brush border, could also be involved.

This work was supported by a grant from the Medical Research Council. We thank Mr Jim Aitken for help with electron microscopy and photography and Miss Bruce and the Sisters and Nursing Staff of the Labour Suite of the Queen Mother’s Hospital, Yorkhill, Glasgow, for co-operation.
