Summary. Spermatozoa from the testis and cauda epididymidis were solubilized by detergent treatment and electrophoresis on SDS polyacrylamide gels revealed that the relative amounts of 13 detergent-extractable proteins decreased during passage of spermatozoa through the epididymis, whereas on cauda epididymal spermatozoa the M₆ values were 47 000, 24 000, 17 000, 14 500 and 13 500. Substantial differences were also noted in the protein composition of rete testis fluid and cauda epididymal plasma. The results support the concept that there is a considerable re-organization of the molecular architecture of the plasma membrane of spermatozoa during maturation in the epididymis.

Introduction

The acquisition of motility and fertilizing capacity by spermatozoa during their maturation in the epididymis is accompanied by structural and biochemical changes to the nucleus, mitochondria, acrosome, and plasma membrane (reviewed by Bedford, 1975). However, relatively little is known about how these changes are mediated, in what sequence they take place, or their relative importance for the ability of a spermatozoon to fertilize an egg. Whole cell labelling techniques (Olsen & Hamilton, 1978; Nicolson, Brodinski, Beattie & Yanagimachi, 1979; Oliphant & Singhas, 1979; Vierula & Rajaniemi, 1980; Voglmayr, Fairbanks, Jackowitz & Colella, 1980; Young & Goodman, 1980; Jones, Pholpramool, Setchell & Brown, 1981; Olson & Danzo, 1981), freeze-fracture analysis (Koehler, 1970; Flechon, 1974; Suzuki & Nagano, 1980), and the binding of lectins and antibodies to membrane antigens (Barker & Amann, 1971; Lea, Petrusz & French, 1978; Moore, 1980; Koehler, 1981; Jones & Brown, 1982) have indicated that there is a significant re-organization of the structure of the sperm plasma membrane during maturation. Although changes to the plasma membrane are probably only one facet of the overall maturation process, it is to be expected that they will have significant consequences for intracellular events, e.g. by regulating membrane permeability.

Several workers have reported an alteration in the protein composition of spermatozoa during epididymal maturation (Lavon, Volcani & Danon, 1971; Brooks & Higgins, 1980; Olson & Danzo, 1981). However, accurate identification and quantitation of these changes and information on the organization of proteins in membranous elements is lacking. The aims of the present investigation therefore, were (a) to document any differences between testicular and epididymal (cauda) rat spermatozoa with respect to the nature of proteins solubilized with detergents, and (b) to compare the disposition of proteins in the plasma membrane by using lactoperoxidase-catalysed iodination techniques.
Materials and Methods

Materials. Adult male Wistar rats (300–350 g body weight) were used. All chemicals and enzymes were of the highest purity available commercially and were purchased from BDH (Chadwell Heath, Dagenham, Essex, U.K.) or Sigma (London) Chemical Co. (Poole, Dorset, U.K.). Glass fibre filters (GF/C) and nitrocellulose were supplied by Whatman Biochemicals (Maidstone, Kent, U.K.). Pharmacia Ltd (Hounslow, Middlesex, U.K.) supplied protein standards of known size: these were α-lactalbumin (Mr = 14 400), soya bean trypsin inhibitor (Mr = 20 100), carbonic anhydrase (Mr = 30 000), ovalbumin (Mr = 43 000), bovine serum albumin (Mr = 65 000) and phosphorylase b (Mr = 94 000). 125I (sp. act. 15-9 mCi/µg) was purchased from Amersham International (Bucks, U.K.).

Collection of testicular and epididymal spermatozoa. Testicular spermatozoa were collected by puncturing the extra-testicular rete testis of rats that had had the efferent ductules ligated for 16–18 h previously. Approximately 100–150 µl testicular fluid per rat were collected; the sperm density was 0-5–1-0 × 10⁸/ml. Spermatozoa were flushed from the cauda epididymidis by retrograde injection of buffered isotonic sucrose (0-264 M-sucrose–5 mM-Hepes pH 7-4) via the vas deferens. A small bubble of air preceded the buffer to prevent undue dilution of the luminal contents. All manipulations were performed with the tissue under a ×8 stereomicroscope. Spermatozoa were pooled from 6–10 animals for each experiment and motility was checked by phase-contrast microscopy.

The luminal contents from the cauda epididymidis were diluted in isotonic sucrose (approximately 40 µl in 1 ml) and 1–2 ml sperm suspension was layered over 3 ml 0-3 M-sucrose–5 mM-Hepes pH 7-4. After centrifugation at 600 g for 10 min the sperm pellet was resuspended to approximately 10⁸ cells/ml in sucrose buffer. Testicular spermatozoa were washed directly as described above without dilution and resuspended in sucrose buffer to approximately 10⁸ cells/ml. Sperm concentration was determined by haemocytometer counts.

Sonication of spermatozoa. Washed spermatozoa were sonicated for 30 sec at 4°C (Kerry’s Ultrasonics, Model KG 100). This procedure decapitated spermatozoa and extensively disrupted plasma membranes.

Preparation of a membrane fraction from spermatozoa. Washed spermatozoa suspended in sucrose were sonicated as described above and centrifuged at 10 000 g for 30 min. The supernatant was removed and centrifuged another 2 times; once at 20 000 g for 30 min and then at 100 000 g for 45 min. The final pellet obtained was regarded as the membrane preparation. Electron microscopy showed that it consisted solely of small membrane-bound vesicles (results not shown).

Iodination of plasma membrane proteins on spermatozoa. Spermatozoa were labelled by the procedure of Hubbard & Cohn (1976). To 1·0 ml of sperm suspension was added 3 µl glucose oxidase (14 m Sigma Units/µl: 0·12 µg protein; i.e. 1 unit will form 1 mg purpuragolin from pyrogallol in 20 sec at pH 6·0 and 20°C), 15 µl lactoperoxidase solution (365 m Sigma Units/µl: 75 µg protein; i.e. 1 unit will oxidase 1 µmol β-D-glucose to D-gluconic acid and H₂O₂ per min at pH 5·1 and 35°C), 5 µl glucose solution (0·56 M) and 50 µCi carrier-free 125I. The above solutions were added as hanging drops on the walls of the test-tube so that they could be mixed simultaneously. Controls contained all solutions except lactoperoxidase. At 1, 2, 5, 10 and 20 min 2 × 20 µl portions were withdrawn, mixed with 100 µl 1·M-potassium iodide in 50 mM-sodium metabisulphite solution followed by excess cold (4°C) 10% trichloroacetic acid (TCA). Precipitated proteins were collected on glass-fibre filters (GF/C), dried, and counted in a gamma counter (Wallac Decem-GTL 300-1000 Series). In some instances precipitated proteins were delipidated by washing filters with 50 ml chloroform : methanol (2 : 1 v/v). The remaining spermatozoa were diluted with 5 volumes of sucrose buffer and washed through 6 ml 0·3 M-sucrose. Supernatants were removed and labelled proteins were extracted from spermatozoa as described below.

Suspensions of labelled sonicated spermatozoa were diluted with 10 volumes of sucrose buffer and centrifuged at 100 000 g for 60 min at 4°C. The clear supernatant was removed, the walls of the
test-tubes wiped dry and the pellet extracted with detergents as described below. Preliminary experiments showed that when intact spermatozoa were treated in an identical fashion the pattern of labelled proteins obtained after separation on SDS polyacrylamide gels was identical to that found when spermatozoa were washed through sucrose.

**Extraction of proteins from spermatozoa.** Spermatozoa were extracted with 0.2% sodium deoxycholate in 0.264 M-sucrose buffer pH 8.0 at 4°C for 45 min and centrifuged at 1000 g for 10 min. The supernatants were removed, re-centrifuged at 10 000 g for 10 min and stored frozen at −20°C. The 1000 g sperm pellets were then re-extracted in 0.5 ml 1.0% SDS in sucrose buffer pH 7.4. Membrane pellets were solubilized directly in 2% SDS in 62.5 mM- Tris/HCl pH 7.4.

**Electrophoresis and detection of labelled proteins.** Proteins were precipitated with 9 volumes of absolute ethanol, centrifuged at 10 000 g for 10 min and the pellets solubilized by boiling for 3 min in 110 µl 62.5 mM-Tris/HCl pH 7.2 containing 1% SDS and 1% 2-mercaptoethanol. A portion was removed for counting or protein determination (by absorption at 280 mm) and equal counts or amounts of protein were applied to each track of a 15% polyacrylamide slab gel containing 1% SDS (Jones, Brown, von Glos & Parker, 1980). Proteins were stained with 0.05% Coomassie Brilliant Blue or Amido Black in an aqueous solution of 40% methanol and 7% acetic acid for 60 min at room temperature, and destained overnight in the same solvent without dye. Relative amounts of protein were quantified by densitometry, using an integrating densitometer (Helena Laboratories) to calculate relative areas. Labelled proteins were detected by autoradiography on pre-flashed film (Kodak X-Omat H) and quantified by densitometry. The results shown are representative of the data as a whole.

**Results**

**Evaluation of cellular integrity**

Initial experiments were designed to evaluate procedures which would wash all unbound extracellular secretions from spermatozoa whilst preserving the integrity of the plasma membrane. The suitability of sucrose-based diluents for preserving the viability of spermatozoa and the efficacy of a sucrose gradient for removing seminal plasma have been investigated for a number of species (Harrison, Dott & Foster, 1978): these procedures remove approximately 99% of extracellular secretions whilst preserving the motility and fertilizing ability of spermatozoa.

To check sperm integrity, we compared the profile of proteins that became iodinated on ‘intact’ spermatozoa with those that became iodinated on spermatozoa that had been damaged deliberately by sonication, the rationale of this being that sonication would expose intracellular membrane-bound proteins, e.g. on the nucleus, acrosome and mitochondria, which would be iodinated in addition to those on the plasma membrane. These intracellular proteins could then be used as markers for assessing cellular integrity. A total of 8 proteins were labelled on intact cauda epididymal spermatozoa when detergent-extracted proteins were separated on SDS polyacrylamide gels (Text-fig. 1). However, approximately 15 proteins were labelled on damaged spermatozoa, indicating that several intracellular membrane-bound proteins had been exposed to lactoperoxidase.

**Comparison of total detergent-soluble proteins in testicular and cauda epididymal spermatozoa**

Preliminary experiments showed that the rate of solubilization of total protein from washed testicular and cauda epididymal spermatozoa incubated in 0.2% deoxycholate reached a plateau after incubation for 45 min at 4°C. A comparison of the profile of proteins extracted with detergent from testicular and cauda epididymal spermatozoa after analysis on 15% polyacrylamide gels containing SDS is shown in Pl. 1, Fig. 1. Approximately 40 proteins, with molecular weights ranging from 12 500 to 110 000, were resolved in the sperm extracts. High molecular weight
proteins (> 120 000) were also observed but were not investigated further. Densitometric estimations of each protein in total detergent extracts (i.e. deoxycholate + SDS), showed that the relative amounts of proteins with molecular weights of about 14 000, 14 500, 16 000, 21 000, 25 500, 27 000, 31 000, 34 000, 37 000, 64 000, 66 000, 84 000 and 94 000 decreased during passage of spermatozoa from the testis to the cauda epididymidis, proteins with molecular weights of about 13 000, 13 500, 17 000, 18 500, 19 000 and 47 000 increased, whilst the remainder showed little or no detectable change.

Comparison of proteins in a membrane preparation from testicular and cauda epididymal spermatozoa

Since detergent extracts of whole spermatozoa contain water-soluble proteins as well as those previously bound to membranes, the type of proteins present in a membrane preparation was investigated. A membrane preparation from testicular spermatozoa showed a different profile of proteins stainable with Coomassie Blue than did a membrane preparation from cauda epididymal spermatozoa (Pl. 2, Fig. 2). A major difference was the presence of relatively large amounts of the M, 21 000 protein in testicular sperm membranes, although such a preparation must have contained membranes from a variety of sources, e.g. acrosome, as well as the plasma membrane, since no attempt was made to purify the latter. The composition of proteins in rete testes fluid and cauda epididymal plasma are also shown for comparison (Pl. 2, Fig. 2, tracks 1 & 2).

Iodination of plasma membrane proteins on testicular and cauda epididymal spermatozoa

The rate of incorporation of $^{125}$I into protein was rapid during the first 5 min for testicular and cauda epididymal spermatozoa (Text-fig. 2), but thereafter it declined sharply with only a 12% increase during the next 15 min. Therefore, in all subsequent experiments iodination was terminated after reaction for 3 min. The incorporation of $^{125}$I into protein in the absence of lactoperoxidase was consistently < 2% of that in the presence of the enzyme. Delipidation of acid-insoluble material collected on filters caused a 24% and 29% decrease in radioactivity associated with testicular and cauda epididymal spermatozoa respectively, suggesting that some of the iodinated proteins are very hydrophobic or are associated with lipids.

Analysis of detergent-extracted proteins on SDS polyacrylamide gels followed by autoradiography revealed a heavily iodinated protein of Mr, ~78 000 on testicular and epididymal spermatozoa (Text-fig. 3). However, further experiments showed that this represented...
Fig. 1. SDS polyacrylamide gel electrophoresis of proteins extracted with sodium deoxycholate (tracks 1 and 2) and SDS (tracks 3 and 4) from intact spermatozoa from the testis (tracks 1 and 3) and cauda epididymidis (tracks 2 and 4). Proteins were stained with Coomassie Blue and values given are approximate molecular weights. Each track received 100 µg protein.
Fig. 2. SDS polyacrylamide gel electrophoresis of proteins in rete testis fluid (track 1), cauda epididymal plasma (track 2) and in a membrane preparation from testicular (track 3) and cauda epididymal spermatozoa (track 4). Proteins were stained with Coomassie Blue and values given are approximate molecular weights. Each track received 100 μg protein.
lactoperoxidase itself (Mr ~ 77 500) which is ‘adsorbed’ non-specifically onto the sperm membrane and then iodinated. This binding of lactoperoxidase to the sperm plasma membrane has not been reported previously, although in several instances when spermatozoa have been iodinated by this technique labelled proteins have been found in the region of Mr 70 000–80 000 (Nicolson et al., 1979; Olson & Danzo, 1981; Wong, Tsang & Lee, 1982). The total amount of lactoperoxidase binding to spermatozoa was in the microgram range as it could be detected with Coomassie Blue; control spermatozoa incubated without lactoperoxidase showed only a small amount of protein in the Mr 78 000 region. It was noticeable that 3–4 times more enzyme bound to testicular spermatozoa than to spermatozoa from the cauda epididymidis. Nonetheless, over and above this artefact there were several important differences between the two types of spermatozoa in the nature of the proteins iodinated. Analysis of deoxycholate- and SDS-extracted proteins from testicular spermatozoa revealed 10 labelled proteins with approximate molecular weights ranging from 14 000 to 150 000 (Text-fig. 3). Neglecting the artefactual labelling of the lactoperoxidase, the most intensely iodinated sperm protein had an Mr of ~ 110 000 and accounted for 32% of the total label incorporated. By contrast, 8 proteins on cauda epididymal spermatozoa were iodinated (Text-fig. 3), only 2 of which, Mr 17 000 and 110 000, corresponded to proteins on testicular spermatozoa.

Text-fig. 2. Time-course of the incorporation of $^{125}$I into total acid-insoluble protein on intact testicular (●) and cauda epididymal spermatozoa (▲) in the presence of lactoperoxidase. ○, △. Incorporation in the absence of lactoperoxidase.

Text-fig. 3. Comparison of membrane-bound proteins which label with lactoperoxidase-$^{125}$I on intact testicular and cauda epididymal spermatozoa after separation on SDS polyacrylamide gels. Labelled proteins were detected by autoradiography and total incorporation of $^{125}$I was calculated by combining densitometric scans of deoxycholate and SDS extracts.
Instead, 60% of the $^{125}$I incorporated was localized in a protein of $M_r \sim 47\ 000$ and 12% in one of $M_r \sim 24\ 000$. Other labelled proteins are shown in Text-fig. 3. More radioactivity was detected in the protein of $M_r 17\ 000$ than in the corresponding protein on testicular spermatozoa whereas the converse was true for the $M_r 110\ 000$ protein. For spermatozoa from both sites, a significant amount of radio-label was associated with high molecular weight proteins ($> 200\ 000$) which did not penetrate the separating gel by more than 1 mm. No attempt was made to identify these proteins.

**Discussion**

An important requirement in all whole cell labelling experiments is that the cell suspension should be homogeneous. Surprisingly, insufficient attention has been paid to this problem and previous workers have collected spermatozoa from the epididymis simply by mincing the tissue in PBS. In our experience spermatozoa obtained in this way are always contaminated with some lymphatic and epididymal epithelial cells and, unless purified further, are unsuitable for experiments of the kind described here. However, spermatozoa collected directly from the rete testis, or flushed from the cauda epididymidis, are consistently of high purity, confirming our belief that any differences we observe between the two cell suspensions reflect changes to spermatozoa alone, and not varying amounts of contaminating tissue cells.

The decrease in the total amount of protein extractable with detergents during maturation of spermatozoa in the epididymis is not a generalized effect but appears to be caused by a loss of specific proteins. The fact that the amount of certain proteins decreases substantially during maturation, e.g. the 21 000 protein, whereas others do not change, e.g. the $M_r 23\ 000$ protein, suggests that they leak out of spermatozoa during passage through the epididymis, or that they are preferentially removed from membranes, or both. The presence of a protein of $M_r 21\ 000$ in a membrane preparation from testicular spermatozoa but its absence from epididymal spermatozoa and secretions argues against its direct removal and accumulation in the luminal fluid during passage of spermatozoa through the epididymis. Lavon et al. (1971) speculated that these changes may be due to proteolytic degradation of membrane proteins, brought about by hydrolytic enzymes in epididymal secretions. If so, then it is highly selective and efficient because none of the proteins removed from testicular spermatozoa are present in cauda epididymal plasma. The epididymis synthesizes a variety of hydrolytic enzymes (Jones, 1978) and it may be that they are secreted in a zymogen form, to be activated later by more favourable conditions of pH or calcium ion concentration, for example.

Significant differences between testicular and cauda epididymal spermatozoa were also apparent in the profile of proteins in a membrane preparation (Pl. 2, Fig. 2). The overall impression was again one of a loss of proteins from membranes during epididymal maturation. The $M_r 23\ 000$ protein, which was a major component in detergent extracts of both types of spermatozoa, was present in relatively small amounts in membrane preparations, suggesting that it is not an integral membrane protein but is easily detached from the cell surface. The $M_r 23\ 000$ protein is a major epididymal secretory protein although it is also present in rete testis fluid (Pl. 2, Fig. 2). We have shown that this protein possesses significant $\alpha$-lactalbumin-like activity (Jones & Brown, 1982). Its position on the cell surface suggests that it may be involved in regulating glycosylation of existing membrane proteins (Hamilton, 1981; Jones & Brown, 1982). By contrast, there was no significant diminution in the relative amounts of the proteins of $M_r 18\ 500$ and $19\ 000$ in membrane preparations from cauda epididymal spermatozoa (compare track 2, Pl. 1, Fig. 1 with track 8, Pl. 2, Fig. 2), suggesting they are firmly bound to the plasma membrane. We have shown these proteins are homologous with the 2 androgen-dependent proteins synthesized and secreted in the caput epididymidis (Jones et al., 1980; Jones & Brown, 1982). It may be, therefore, that some epididymal secretory proteins are fully integrated into the plasma membrane during maturation whereas others are only loosely attached.
Although several workers have used lactoperoxidase-catalysed iodination techniques to label membrane proteins on spermatozoa, there have been few attempts to ascertain if the enzymic labelling was confined solely to the cell surface or to optimize the reaction conditions without affecting cell viability. If the plasma membrane of a small proportion (~5%) of cells is permeable and lactoperoxidase has access to intracellular proteins then spurious results can be obtained (Juliano & Behar-Bannelier, 1975), especially if the intracellular proteins label with higher specific activity than the plasma membrane proteins. This emphasizes the need to include controls consisting of cells that have been damaged deliberately to help identify those intracellular proteins that are susceptible to iodination, and then to use these proteins as markers for assessing membrane permeability. Furthermore, the deleterious effects of H2O2 and iodination on membrane proteins and lipids should be seriously considered in view of reports of lipid peroxidation (Welton & Aust, 1972), cell cytotoxicity (Edelson & Cohn, 1973) and loss of viral infectivity (Brewer & Singer, 1974) after iodination. As little as 5 µM-H2O2 added to liver microsomes caused significant lipid peroxidation and inhibition of cytochrome P450 (Welton & Aust, 1972). In view of the toxicity of H2O2 to spermatozoa (VanDemark, Salisbury & Bratton, 1949; Wales, White & Lamond, 1958) and the unusual lability of their lipids to peroxidation (Jones & Mann, 1976) it was important to investigate conditions which would avoid membrane perturbation and the possibility of labelling intracellular membrane proteins, whilst ensuring adequate incorporation of 125I. Our results show that, when the glucose-glucose oxidase system is used to generate a continuous micromolar supply of H2O2 close to its rate of consumption, nearly maximum incorporation of 125I into protein is obtained within 3 min. The enzymic system also eliminates the periodic addition of small quantities of concentrated H2O2 which might cause transient gradients of harmful amounts of peroxide.

More proteins were iodinated on spermatozoa damaged by sonication than on spermatozoa whose integrity had been preserved. This suggests that these additional proteins are located on intracellular membranes or that sonication ‘exposes’ in some way proteins on the plasma membrane not normally available to lactoperoxidase. In view of the presence of significant amounts of intracellular membranes, e.g. acrosomal membranes, it is likely that many of these additional labelled proteins are internal to the plasma membrane. In none of our experiments with intact spermatozoa did we observe iodination of the 7 additional proteins found after sonication.

The significant differences between testicular and cauda epididymal spermatozoa in the nature of the proteins iodinated suggest a substantial re-organization of the plasma membrane during maturation. Many plasma membrane proteins may not label because of the lack of exposed tyrosine or histidine residues or other problems associated with this technique (Hubbard & Cohn, 1976). Nonetheless, the fact that on testicular spermatozoa the most heavily labelled proteins have molecular weights of approximately 110,000, 94,000, 84,000 and 55,000 whereas on cauda epididymal spermatozoa only proteins with molecular weights of approximately 47,000, 24,000, 23,000, 17,000, 14,500 and 13,500 incorporate 125I is indicative of real organizational changes. Many of the proteins that became strongly iodinated were relatively minor components of the total detergent-extractable protein as judged by their ability to bind Coomassie Blue. Identification of the M, 47,000 protein as the androgen-dependent protein synthesized specifically in the cauda epididymis (Jones et al., 1980) is tentative and must await immunological verification. It will be important in future work to determine the orientation of proteins in the plasma membrane, the sequence and precise region of the epididymis where the organizational changes are effected, and ultimately their relationship to the acquisition of motility and fertilizing ability by spermatozoa.

We thank Mrs M. Mansfield and Mrs J. Constable for typing the manuscript.
