Addition of androgens to cultured hamster epididymis increases zona recognition by immature spermatozoa

Patricia S. Cuasnicú, Fernanda González Echeverría, Alejandra Piazza and J. A. Blaquier

Instituto de Biologia y Medicina Experimental, Obligado 2490, 1428 Buenos Aires, Argentina

Summary. The ability of spermatozoa recovered from the successive segments of the hamster epididymis to bind to the zona pellucida was studied and a major increase was found as spermatozoa passed from the proximal to the distal portions of the corpus epididymidis (1.95 compared with 20 spermatozoa bound/egg). Tubules from the proximal epididymis were cultured in conditions which preserved the motility of the contained spermatozoa for 48–72 h. Addition of 2 μM-5α-DHT to the culture medium for 17 h stimulated the incorporation of 3H-labelled amino acids into several protein bands whose mobility in polyacrylamide gel electrophoresis was coincident with those of glycoproteins EP1–EP6, previously identified as androgen-dependent in the hamster epididymis in vivo. Examination of the material extracted from washed spermatozoa with 0.5 M-NaCl revealed the presence of radioactive proteins on spermatozoa. The zona-binding ability of spermatozoa from androgen-treated cultured proximal corpus tubules was significantly increased (P < 0.001) as was the no. of spermatozoa/egg (5–51) compared with the value for control cultures (0.87 spermatozoa/egg).

We suggest that androgen-dependent epididymal secretory proteins that associate with spermatozoa might participate in the formation or activation of a site for zona pellucida recognition in the sperm surface.

Introduction

The participation of androgen-dependent epididymal factors in the process of sperm maturation and the recognition that the sperm plasma membrane is the site where most maturational changes occur (see Orgebin-Crist, Danzo & Davies, 1975; Bedford, 1975, for reviews), have stimulated research aimed at finding a role for epididymal secretory products in this process. The association of epididymal glycoproteins to spermatozoa has been described for several species (Cameo & Blaquier, 1976; Lea, Petrusz & French, 1978; Vierula & Rajaniemi, 1980; Voglmayr, Fairbanks, Jackowitz & Colella, 1980; González Echeverría, Cuasnicú & Blaquier, 1982), but the physiological significance of this interaction remains unknown.

Since glycoproteins are known to be involved in cell–cell recognition phenomena (Hughes & Sharon, 1978; Frazier & Glaser, 1979), epididymal secretory glycoproteins could be associated with the assembly or activation of the site for oocyte recognition on the sperm surface.

Recent reports by Saling (1982) and Fournier-Delpech, Courtens, Pisselet, Delaleu & Courot (1982) stress the importance of the development of the ability to bind to the zona pellucida as a determinant of the increasing fertility of spermatozoa during epididymal maturation. We have observed similar increases in the ability of human spermatozoa, obtained from successive epididymal segments, to bind to the vitelline membrane of zona-free hamster oocytes (Hinrichsen & Blaquier, 1980).
In the present study we have determined the profile of zona pellucida binding ability for spermatozoa from each successive segment of the hamster epididymis, and used an organ culture technique to study the effect of androgens upon glycoprotein synthesis and association with spermatozoa.

Materials and Methods

**Animals.** Adult male (8–12 weeks old) and immature female (5–7 weeks old) golden hamsters (*Mesocricetus auratus*) were maintained in 14 h light/24 h. Females were induced to superovulate by injection of 30 i.u. PMSG followed by 40 i.u. hCG 48–72 h later. The oviducts were flushed with Brinster’s (1965) BMOC balanced salt solution 17 h after injection of hCG to recover the oocytes.

**Organ culture.** A technique previously used for the rat epididymis (Blaquier, 1973) was modified. Epididymides were removed under sterile conditions and separated into different segments as described by Horan & Bedford (1972). After removing the capsule, the corpus segment was sectioned as small explants. Avoiding dissection minimized the release of spermatozoa through punctured tubules in this segment. The tissues were cultured for 1–3 days at 33°C in Medium 199 with Earle’s salts (GIBCO, Grand Island, NY, U.S.A.), supplemented with 100 i.u. penicillin/ml and 100 µg streptomycin/ml and using 95% O₂ and 5% CO₂ as the gas phase. When indicated, 5α-dihydrotestosterone (5α-DHT) (0.1–2 µM) or the 3α- and 3β-isomers of 5α-androstan-3,17β-diol (2 µM) were added to the medium. Cyproterone acetate (courtesy of Schering AG, Berlin, West Germany) was used at a final concentration of 4 µM.

**Protein synthesis assay.** The tubules were cultured for 27 h (with one medium change) in amino acid-free BMOC instead of Medium 199. Fresh medium containing 1 mM-methionine and 3H-amino acid mixture (uniformly labelled, New England Nuclear, 10 µCi/plate) was added and the incubation continued for 17 h. One half of the culture plates, selected at random, also received 5α-DHT during this last period.

The tubules were extensively washed, coarsely chopped with scissors and the spermatozoa released into BMOC. The tissue was then homogenized in 3 volumes of 5 mM-Tris–38 mM-glycine buffer, pH 8.3, and centrifuged at 105 000 g for 60 min to obtain the cytosol. Spermatozoa were washed 3 times by suspension and centrifugation in BMOC and then extracted with BMOC made 0.5 M in NaCl for 30 min at room temperature. The extract was dialysed for 72 h against Tris-glycine buffer and both this preparation and the cytosol were analysed by electrophoresis in 10% polyacrylamide gel slabs as previously reported (González Echeverría et al., 1982). The gels were sliced at 1 mm intervals, dissolved in 150 µl 30% H₂O₂ and counted. When required, gels were stained with Coomassie Brilliant Blue.

**Zona pellucida binding test.** Spermatozoa from fresh or cultured tubules were released into 0.5 ml prewarmed (37°C) BMOC, supplemented with 1 mg glucose/ml and 0.5% bovine serum albumin, and diluted to a concentration of 10⁶ cells/ml. Some (20 µl) of this suspension was added to 20 µl BMOC containing about 10 hamster oocytes, which had been incubated in BMOC for 2 h and in 0.1% hyaluronidase for 5–10 min to remove cumulus cells. The gametes were incubated under a layer of mineral oil for 40 min at 37°C with a gas phase of 95% O₂ and 5% CO₂ and with shaking (50 oscillations/min). Oocytes were then washed 3 times by transference into fresh medium, using a finely drawn pipette as described by Hartmann & Gwatkin (1971) to remove loosely attached spermatozoa. The number of spermatozoa firmly bound to the zona pellucida was then determined in the unfixed sample. Our experience established that 20 spermatozoa/egg was the limit at which the number of spermatozoa bound to a single oocyte could be reliably determined. To minimize error due to individual variations, paired samples (tissue from the same animal) were used in every experiment involving comparison of binding activity of spermatozoa derived from tubules cultured under different conditions. Results were analysed with the χ² test (distribution of oocytes with different numbers of bound spermatozoa) or the Mann–Whitney test (mean number of spermatozoa bound per egg) for statistical significance.
Artificial insemination. The technique described by Horan & Bedford (1972) was used to inseminate immature females induced to superovulate.

Results

Zona pellucida binding activity of spermatozoa from different epididymal segments

The results summarized in Table 1 show that while caput spermatozoa were totally unable to recognize and bind to oocytes, this ability was present in some cells recovered from the proximal corpus epididymidis and increased abruptly when spermatozoa passed into the distal corpus and cauda. This pattern was also reflected in the mean number of spermatozoa bound per egg.

These results indicated that a major change occurred in the ability of spermatozoa to recognize oocytes during passage from the proximal to the distal portions of the corpus epididymidis. Subsequent studies therefore involved the proximal corpus epididymidis.

Epididymides were separated into different segments and the spermatozoa were released into prewarmed BMOC and diluted to 10⁶ cells/ml. Aliquots were incubated with cumulus-free hamster oocytes for 40 min at 37°C with agitation, as described in ‘Methods’. The number of spermatozoa bound to oocytes after 3 passages of the gametes through a finely drawn pipette was determined in the unfixed sample. Results are the mean of 4 experiments.

Organ culture of epididymal tubules

A set of experiments was undertaken to establish the appropriate conditions for the survival of the tissue and of spermatozoa contained in the cultured tubules. In this initial instance, the subjective estimation of the motility of spermatozoa released from the cultured tubules, compared with that of spermatozoa freshly obtained from the same segment, served as an index of viability. Spermatozoa recovered from the proximal corpus (equivalent to segment b of Horan & Bedford, 1972) exhibited undiminished motility for up to 48 h of culture and then a minor decrease at 72 h.

When tubules from other segments were similarly cultured, spermatozoa from the caput and distal corpus were adversely affected by the culture procedure; motility comparable to control values was maintained for only 24 h and severely diminished after longer periods. Spermatozoa from the cauda tubules retained motility for 48 h.

To characterize the system further experiments were conducted to detect whether the culture procedure affected the fertilizing ability of spermatozoa. However, since spermatozoa from the proximal corpus epididymidis are mostly infertile (Horan & Bedford, 1972), spermatozoa obtained from control (no culture) and cultured (24 h) tubules of the cauda were used. After artificial insemination in vivo, control spermatozoa fertilized 91/94 (96%) oocytes while spermatozoa from cultured tubules fertilized 76/90 (84%) oocytes (P > 0.05). These results suggest that the culture procedure used was adequate to maintain spermatozoa contained in proximal corpus and cauda tubules for periods of 24-48 h.
Effect of androgens on the synthesis of epididymal glycoproteins and their association with spermatozoa

Tubules from the proximal corpus segment were cultured in BMOC containing $^3$H-labelled amino acids with and without the addition of 2 µM-5α-DHT. The incorporation of label into macromolecules was examined by polyacrylamide gel electrophoresis of the cytosol and spermatozoa extract. Text-figure 1 shows the patterns obtained when the ratio of radioactivity incorporated in 5α-DHT-treated cultures/control was plotted for each gel slice. Analysis of the profile indicated that the presence of androgen in the culture medium stimulated the incorporation of labelled amino acid into 6 cytosol bands (Text-fig. 1a). The electrophoretic mobilities of these peaks were coincident with those of glycoproteins EP$_1$ to EP$_6$, whose synthesis was stimulated by androgen administration in vivo (González Echeverría et al., 1982).

When the 0.5 M-NaCl extract of spermatozoa obtained from these cultures was examined (Text-fig. 1b), several labelled proteins were again seen. The two main bands in this extract had an electrophoretic mobility coincident with those of glycoproteins EP$_2$ and EP$_3$ and minor radioactive peaks coincident with EP$_4$ and EP$_5$ were also observed.

Text-fig. 1. Effect of androgen on the synthesis of hamster epididymal proteins and their interaction with spermatozoa (a) cytosol and (b) sperm extract. The broken line is the average ratio in the whole gel. The schematic representation of a gel (middle) depicts the electrophoretic mobilities of androgen-dependent glycoproteins EP$_1$–EP$_6$ (González Echeverría et al., 1982) in this system. ALB = albumin, BPB = bromophenol blue.
Effects of androgens on ability of spermatozoa to bind to the zona pellucida

Proximal corpus tubules were cultured for 24 h in the presence or absence of 5α-DHT and the ability of the spermatozoa to bind to the zona pellucida was tested. No significant changes were obtained when 5α-DHT was present in the range 0.1 to 1 µM, but at 2 µM a significant increase in zona binding ability was observed (Table 2). To test whether the effect of 5α-DHT was specific, other androgens, such as the 3α- and 3β-isomers of 5α-androstan-3,17β-diol, were also used at 2 µM, but binding did not differ from control values. Proximal corpus tubules were also cultured in the presence of 2 µM-5α-DHT with and without the simultaneous addition of cyproterone acetate (Table 3). The antiandrogen produced a significant decrease in the zona-binding ability of spermatozoa when compared with cultures to which only 5α-DHT was added.

Experiments were performed as described in Table 2. Results are the mean of 19 independent observations. Compared with values for 5α-DHT treatment: *P < 0.02, **P < 0.01.

Discussion

Fertilization involves a process of specific cell–cell recognition, adhesion and fusion mediated by complementary surface structures present in both gametes. "Bindin" has been identified as the protein responsible for the recognition and adhesion of spermatozoa to sea-urchin eggs (Vacquier & Moy, 1977) and the complementary spermatozoa receptor on the surface of the eggs was also identified (Aketa, Tsuzuki & Onitake, 1968; Schmell, Earles, Breaux & Lennarz, 1977; Glabe & Vacquier, 1978). Evidence for a sperm receptor in the mammalian zona pellucida was initially presented by Gwatkin & Williams (1977) for hamster and mouse eggs, while Bleil & Wassarman (1980) isolated a glycoprotein in mouse zonae pellucidae which possessed receptor activity for spermatozoa. The existence of its counterpart, the sperm plasma membrane receptor-for-zona pellucida has been postulated for the boar (Peterson, Russell, Bundman & Freund, 1979) and the guinea-pig (Yanagimachi, Okada & Tung, 1981). Since this receptor seems to be absent, or at least
inactive, in immature spermatozoa, as implied by the lack of oocyte recognition and binding by spermatozoa recovered from the proximal segments of the epididymis in the mouse (Saling, 1982), ram (Fournier-Delpech et al., 1982) and hamster (this study), it seems likely that the receptor is assembled or activated during maturation.

Glycoproteins secreted by the epididymal epithelium and incorporated onto spermatozoa have been demonstrated for numerous species (Cameo & Blaquier, 1976; Lea et al., 1978; Vierula & Rajaniemi, 1980; Voglmayr et al., 1980) and are likely candidates for the proposed receptor in view of the key role played by these molecules in intercellular recognition and adhesion processes (Hughes & Sharon, 1978; Frazier & Glaser, 1979). In the hamster, such glycoproteins have been identified by Moore (1980) and González Echeverría et al. (1982) and have tentatively been shown to be involved in pre-fertilization events because specific antibodies against them significantly reduced fertility (Moore, 1981).

The experiments described in this report provide further evidence in favour of a biological role of epididymal proteins in sperm maturation. Our results show that the response of the cultured epididymal tubules and their contained spermatozoa to androgenic stimulation in vitro is qualitatively similar to that obtained by testosterone injection into castrated hamsters (González Echeverría et al., 1982), at least from the point of view of the stimulation of the synthesis of glycoproteins EP₁–EP₆ and their deposition on spermatozoa. The two main proteins associated with spermatozoa from androgen-stimulated cultures, tentatively identified as EP₂ and EP₃ based on their similar electrophoretic migration only, are those identified as being added to spermatozoa during epididymal transit and maturation (González Echeverría et al., 1982). However, our most relevant result is that the sperm population derived from tubules exposed to androgens developed a significantly greater ability for oocyte recognition when epididymal glycoproteins EP₂–EP₃ were added to the sperm surface.

The results of Saling (1982) for the mouse and Fournier-Delpech et al. (1982) for the ram show the apparent parallelism between the development of zona-binding activity and fertilizing ability of spermatozoa during epididymal transit. Our results for hamsters agree with this observation, since the major increase in oocyte binding ability detected as spermatozoa pass from the proximal to the distal corpus epididymidis is coincident with the increase in fertility found by Horan & Bedford (1977). Our results support the hypothesis that androgen-dependent secretory epididymal proteins participate in the assembly or activation of a site for oocyte recognition on the sperm surface that occurs during maturation.
