Luminal secretion of *myo*-inositol by the rat epididymis perfused *in vitro**

National Research Institute for Family Planning, Beijing, Peoples' Republic of China

Summary. A technique for perfusing the lumen of rat epididymal tubules maintained *in vitro* showed that [³H]inulin was largely excluded from the lumen of unravelled tubules from the cauda and tubules from the corpus if the connective tissue capsule was removed. The preparation transported [³H]inositol from the bath fluid for 3 h against a concentration gradient in both regions with activity rising (16–29% of bath fluid values) in the cauda and reaching a plateau (18%) in the corpus epididymidis. HPLC showed that radioactivity was solely associated with inositol and its movement to the lumen was reduced by raising inositol in the bath fluid from 50 μM (plasma levels) to 10 mM, but not affected by reducing the glucose concentration in the bath fluid or introducing physiological concentrations of inositol (30 mM) into the lumen. Secretion into the caudal lumen of unlabelled inositol measured by g.l.c. was maintained for 3 h at concentrations (300 μM) greater than those in the bath fluid and was not reduced when glucose or inositol were removed from the bath. In contrast, glucose was only detectable in the lumen when it was present in the bathing medium, reaching 1% of this concentration. Radioactivity appeared in the epididymal lumen reaching a plateau (19% of bath fluid values) in the corpus and cauda when [³H]glucose was added to the bath fluid, but no radiolabelled inositol was found in the lumen. We conclude that epididymal tissue is a major source of secreted inositol.

Introduction

The high concentration of inositol in the epididymal lumen (Hinton, White & Setchell, 1980) arises from concentration of inositol in testicular fluid by water resorption (Setchell & Hinton, 1981), entry from the blood-stream (Hinton & Howards, 1982) and secretion from an epithelial pool (Cooper, 1982). The extent of *myo*-inositol synthesis from glucose by the epididymis is debated (Eisenberg & Bolden, 1964; Robinson & Fritz, 1979; Maeda & Eisenberg, 1980; Hasegawa & Eisenberg, 1981) and although the potential exists, the contribution from luminal spermatozoa is not established (Roberts, Scouten & Nyquist, 1976; Loewus, Wright, Bondioli, Bedgak & Karl, 1983). Investigation of the relative importance of these possible sources would be facilitated by study of glucose uptake and conversion to inositol *in vitro*.

Luminal perfusion of a sperm-free epididymis has certain advantages over micropuncture in the study of epididymal function because spermatozoa, which may contribute to secretion, are removed and control of luminal fluid composition, which may affect transport across the epithelium, is permitted (Cooper & Waites, 1980; Yeung, Cooper & Waites, 1980). Transport studies would be further advanced if altering the composition of fluid bathing the tubules were possible, but this cannot easily be achieved *in vivo*. In-vitro experiments have shown that extratubular compounds influence uptake of carnitine into isolated tubules (Johansen & Bøhmer, 1979), but the location of tracers within the tissue could not be ascertained. Two reports of in-vitro

luminal perfusion have indicated that ions and amino acids enter the proximal and distal epididymal lumen of boars and rats under both stop-flow and continuous perfusion (Dacheux, 1980; Wong, Au & Ngai, 1980), but the extent to which entry of macromolecules reflected leakage of tubules damaged during dissection was not evaluated.

The present experiments were aimed at developing an in-vitro preparation which could be used to study both intra- and extra-tubular influences on the secretion of inositol and in particular to determine whether extratubular glucose is a precursor of secreted inositol.

Materials and Methods

Animals and procedure. Wistar-strain rats (mean $\pm$ s.d. body weight 367 ± 66 g) had access to rat pellets (Institute of Genetics, Beijing) and water *ad libitum*, and were kept in 14 h light/24 h at 18–22°C. Animals were anaesthetized with urethane (ethyl carbamate, 1 g/kg) and sequentially each epididymis was transferred to ice-cold medium, stripped of adhering fat and the distal cauda and mid-corpus were separated. In all experiments the outer connective tissue capsule was rapidly but carefully removed and the lobes of tubule coils were gently pulled apart along natural planes of cleavage. In some experiments further unravelling of the tubule was accomplished. The distal end of the tubule was cannulated with polyvinylchloride tubing (0.5 mm i.d., 0.8 mm o.d.; Dural Plastics Pty & Eng Co., Dural, New South Wales, Australia) or polyethylene tubing (0.6 mm i.d., 1.0 mm o.d.; Intramedic, Clay-Adams, Parsippany, NJ, U.S.A.) the diameters of which were reduced over a flame to approximate the diameter of the tubule to be cannulated, and tied in place with 4/0 silk thread suture for the cauda or 7/0 thread for the corpus. After flushing out the luminal contents with solutions subsequently used in the perfusion (intraluminal fluid) another cannula was inserted into the more proximal end and secured with 7/0 thread (Barraquer, John Weiss & Son Ltd, London W1H 0DN, U.K.). When necessary, about 150 μ l of perfusing solution were flushed through manually in 1–2 min and aliquants of the last flush-out fluid were collected. About 45–60 min after removal from the animal the sperm-free cannulated tubule was transferred to a 20-ml water-jacketed organ bath (Harvard Apparatus Ltd, Edenbridge TN6 6HE, U.K.) maintained at $33 \pm 1^\circ\text{C}$ and containing fluid continuously bubbled with air drawn through a Millipore filter (0.45 μ m pore diameter). Continuous perfusion through the lumen was maintained at a nominal rate of 1 μ l/min (Harvard Infusion pump, Model 975A, South Natick, MA, U.S.A.); at this rate the times needed for complete flow through the entire corpus and cauda tubules were about 6 and 25 min respectively. The outflowing perfusate was collected every 30 min into preweighed vials to ascertain exact perfusion rates. At the end of the experiment the tubules were fixed by luminal injection of 1.5% aqueous glutaraldehyde containing 0.1% amido black 10B in 7% acetic acid (v/w/v), unravelled and their lengths were measured.

Solutions. All chemicals were from the Sigma Chemical Company (Poole BH17 7NH, U.K.) unless otherwise stated. The bath fluid consisted of 127 mM-NaCl, 2.7 mM-KCl, 8.1 mM- Na_2HPO_4 , 1.5 mM- KH_2PO_4 , 0.1 mM- Na_4EDTA , 0.5 mM- MgSO_4 , 0.8 mM- CaCl_2 , 5 mM-D-glucose, 10 mM-sodium DL-lactate, 5 mM-sodium pyruvate, 50 μ M-*myo*-inositol, 30 μ M-L-carnitine (a gift from Sigma Tau, Industrie Farmaceutiche Riunite SPA, 0014 Rome, Italy), 1 mg bovine serum albumin/ml, 50 ng testosterone/ml (final ethanol concentration 0.005% v/v) with 50 i.u. K^+ penicillin/ml and 50 i.u. streptomycin sulphate/ml; the osmolarity was 305 mosmol/kg water and the pH was 7.4. Intraluminal fluid for the cauda contained 13 mM-NaCl, 50 mM-KCl, 2.6 mM- CaCl_2 , 1.1 mM- MgSO_4 , 18 mM-N-morpholinopropanesulphonic acid and was adjusted to pH 6.9 with 7 mM-NaOH. To raise the osmolarity to 340 mosmol/kg water, 77 mM-choline chloride was included. The solution used for the corpus was similar but concentrations were adjusted to 51 mM-NaCl, 37 mM-KCl and 80 mM-choline chloride. Composition of the bathing medium was altered by omitting or reducing glucose to 0.5 mM or increasing *myo*-inositol to 10 mM with isosmotic changes in the

amount of NaCl. The intraluminal fluid was altered by adding 30 mM-*myo*-inositol or 25 mM-glucose and making isosmotic reduction in choline chloride.

Isotopes and liquid scintillation counting. The following isotopes from Amersham International (Amersham HP7 9LL, U.K.) were added to the bath fluid at the following concentrations and final specific activities: [^3H]inulin (0.3 $\mu\text{Ci/ml}$; 2.42 Ci/mol), *myo*-[2- ^3H]inositol (0.75 $\mu\text{Ci/ml}$; 15 and 0.075 Ci/mol) and D-[2- ^3H]glucose (0.8 $\mu\text{Ci/ml}$: 0.16, 1.6 and 17000 Ci/mol). Duplicate 10 μl aliquants of outflowing perfusate, inflowing perfusate and bath fluids were transferred to 5 ml or 2 ml scintillation fluid (5.5 g PPO, 0.1 g POPOP per litre of toluene: Triton X-100 67:33, v/v) giving unquenched efficiencies for ^3H of 32% and 37% respectively. Radioactivity was monitored on an LKB Rackbeta 1217 with quench correction by external standardization. Remaining samples were pooled and frozen at -70°C . Results were expressed as concentrations of radioactivity in the luminal perfusate as a percentage of that in the bath, or corrected for length of the tubule. When plateau values were attained mean values for the period were calculated for each epididymis. Statistical analysis was by Student's *t* test. Transport rates of inositol and glucose were calculated from the perfusion rate, concentration of isotope in the lumen and the specific activity in the bath.

High-performance liquid chromatography (HPLC). Separation of radiometabolites was effected by HPLC using a Perkin-Elmer Series 3B chromatograph, a 25 cm $\times$ 4.6 mm column of Silica B-5 (7 μm , Perkin-Elmer) with a 2 cm guard column of LC-Si (Supel Co. Inc.). Isocratic elution at 2 ml/min and 20°C was by acetonitrile (Merck HPLC grade): water (deionized, triple-distilled): tetra-ethylene pentamine (reagent grade, Shanghai First Reagent Factory) (72:28:0.02, by vol.) made to pH 8.9 with acetic acid. Detection of eluting substances was by a differential refractive index monitor (Laboratory Data Control, Model 11071, NH, U.S.A.). Pooled samples of perfusates and bath, deproteinized with 2 volumes of ethanol, were concentrated by freeze-spinning (Labconco Corp., Kansas City, MO, U.S.A.) and taken up in water. After centrifugation at 13000 g_{max} for 5 min, 20–25 μl were injected and fractions were collected with an LKB Ultrarac 2070 at 0.3-min intervals at the outflow of the refractive index monitor. From each fraction, 0.5 ml with 0.5 ml water, or 0.15 ml, was added to 5 ml or 2 ml scintillant respectively for estimation of tritium.

Gas-liquid chromatography (g.l.c.). Samples were deproteinized with two volumes of ethanol containing 20 or 100 nmol internal standard (methyl-4,6-*O*-benzylidine α -D-glucopyranoside, MBG) and supernatants were taken to dryness *in vacuo* over P_2O_5 . After addition of 25–50 μl silylating reagent (trimethylsilylimidazole (Janssen Chimica, B-2340 Beerse, Belgium): dry toluene, 1:2, v/v), samples were heated at 45°C for 60 min before injection. Silyl derivatives of carbohydrates were quantified by g.l.c. on a Shimadzu GC-RIA. Separation was effected in 2.6 m $\times$ 3 mm glass columns of 3% SE-30 on Gas Chrom Q (80–120 mesh) and detection was by flame ionization. Filtered carrier gas (N_2), hydrogen and air were supplied at 60, 47 and 300 ml/min respectively. The detection temperature was 250°C and the oven temperature was programmed to rise after 8 min at 190°C to 210°C at 3.5°C/min . This separated α - and β -glucose from inositol (retention times 0.449, 0.622 and 0.814 relative to MBG). Over the range 10–100 nmol, recoveries of glucose and inositol were 108% and 105% and coefficients of variation between assays were 9.2% and 9.0%, respectively.

Results

Movement of radio-labelled compounds to the lumen

[^3H]Inulin. Tritium appeared in the lumen from the bath solutions containing [^3H]inulin. In the cauda (mean $\pm$ s.d. perfused length 17.0 ± 4.7 cm) there was little difference in the extent of entry whether the tubules were unravelled (5.8% of the bath fluid values at 3 h) or not (4.1%) and the pooled results are plotted in Text-fig. 1. By contrast, the corpus epididymidis (length 8.6 ± 1.8 cm)

Tubules were unravelled (●) or with capsule only removed (○). Each point is the mean $\pm$ s.e.m. for the no. of experiments indicated in parentheses.

Text-fig. 2. The concentration of radioactivity in fluid in the epididymal lumen during perfusion *in vitro* expressed as a percentage of that in the bath fluid containing [^3H]inositol for epididymal tubules of (a) the corpus and (b) the cauda. □, ○: Inositol-free fluid in the lumen and bath fluid containing 5 mM-glucose and 50 μM (□) or 10 mM (○) inositol. ■, ●: Glucose-free bath medium containing 50 μM -inositol and fluid in the lumen containing either no inositol (■) or 30 mM-inositol (●). Each point is the mean $\pm$ s.e.m. for the no. of experiments indicated in parentheses.

proved to be delicate and unravelling the tubule resulted in significantly greater radioactivity in the lumen (3.3% bath fluid values by the end of the 2nd hour of perfusion) than if the tubules were not unravelled (0.9%, $P < 0.05$) and this trend continued over the next hour (see Text-fig. 1). In all subsequent experiments, therefore, only the capsule was removed from the corpus epididymidis.

[³H]Inositol. In medium of composition similar to that of blood plasma and containing 50 μ M-inositol and 5 mM-glucose, radioactivity entered the caudal lumen (length 17.0 ± 4.3 cm) to reach levels at the end of 3 h (28.5% those of the bath fluid) that were significantly greater than those obtained after 1 h (16.4%; $P < 0.01$), a gradual increase of 2.4–4.0% of bath fluid values per 30-min period (see Text-fig. 2). In contrast, radioactivity in the corpus lumen (9.0 ± 3.0 cm long) reached a plateau over the same period (17.7–22.8% of bath fluid values, mean 20.6%) but was not significantly different from entry into the cauda at any time. When results were expressed per unit length, entry into the corpus only significantly exceeded that into the cauda up to 1.5 h ($P < 0.05$).

When the concentration of inositol in the bath was raised to 10 mM there was a 60–70% reduction in movement of tracer to the lumen in both the cauda and corpus epididymidis, and between 1 and 2.5 h activity reached a plateau 6.7–7.8% bath (mean 7.4%) in the cauda which was not different from that (7.3–8.6%, mean 7.7%) in the corpus (Text-fig. 2). There was no difference in the uptake of [³H]inositol in the cauda from glucose-free bath solutions containing 50 μ M-inositol (17.5–26.2% of bath fluid values from 1–3 h perfusion, rising at 1.8% of the bath fluid value per 30 min) or those in the presence of glucose (Text-fig. 2b). However, there was consistently less transport of [³H]inositol when 30 mM-inositol was added to solutions perfusing the caudal lumen, but this was only significant ($P < 0.05$) at 1 h; thereafter activity continued to increase in the lumen at 2% of bath fluid values per 30 min (Text-fig. 2b).

[³H]Glucose. Entry of radioactivity to the caudal lumen (16.6 ± 3.9 cm long) from solutions containing 5 mM-glucose reached a plateau at 17.3–19.7% (mean 18.9% of bath fluid values). Lowering the glucose concentration to 0.5 mM increased entry, and when no glucose additional to the tracer was added to the bath fluid, significantly greater amounts of radioactivity reached the lumen by 2–3 h ($P < 0.001$). Entry into the corpus epididymidis (6.3 ± 2.8 cm long) was similar (mean 19.4%) to that in the cauda; but there was no consistent trend in transport when glucose concentrations were varied (Text-fig. 3). When glucose was present in the cauda epididymal lumen (25 mM) movement of tracer to the lumen was consistently increased (Text-fig. 3) and significantly so at 0.5 and 1 h ($P < 0.05$), reaching a value obtained in glucose-free media.

Text-fig. 3. The concentration of radioactivity in fluid in the rat epididymal lumen during perfusion *in vitro* expressed as a percentage of that in the bath fluid containing [³H]glucose for epididymal tubules of (a) the corpus and (b) the cauda. $\circ$, $\square$, $\triangle$: Glucose-free fluid in the lumen and bath fluid containing 50 μ M-inositol and 50 mM ($\square$), 500 μ M ($\triangle$) or 5 mM ($\circ$) glucose. $\bullet$, Bath fluid containing 5 mM-glucose and 50 μ M-inositol and fluid in the lumen containing 25 mM-glucose. Each point is the mean $\pm$ s.e.m. for the no. of experiments indicated in parentheses.

Analysis of radiometabolites

The HPLC procedure employed adequately separated glucose (retention time 5 min 08 sec–5 min 13 sec) and *myo*-inositol (8 min 06 sec–8 min 14 sec) from the solvent front (1 min 59 sec–2 min 02 sec). Labelled standards added to the perfusing solution co-chromatographed with unlabelled compounds, fractions being collected slightly later than mass peaks owing to the dead space between the refractive index detector and fraction collector ($[^3\text{H}]\text{glucose}$ at 5 min 06 sec–5 min 24 sec and $[^3\text{H}]\text{inositol}$ at 8 min 06 sec–8 min 24 sec).

$[^3\text{H}]\text{Inositol in bath}$. The majority of radioactivity in the bath at the end of the 3-h perfusion migrated with *myo*-inositol and accounted for 92% of the total radioactivity. Only one peak of activity comigrating with authentic inositol appeared in the perfusates from the corpus and cauda, accounting for 91% of the total activity in the cauda and 84% in the corpus from pooled perfusates, and 79% in the cauda in one experiment in which all the perfusate was collected for metabolite analysis.

$[^3\text{H}]\text{Glucose in bath}$. One major peak of radioactivity which migrated with $[2\text{-}^3\text{H}]\text{glucose}$ was present in the bath and comprised 81% of the total bath activity. By contrast, two major peaks of radioactivity were present in the perfusates from both corpus and cauda. Of these, the major peak comigrated with glucose (44 and 55% total luminal activity in cauda (2 exps) and 59% in corpus). The smaller peak eluted at 9 min 18 sec–10 min 12 sec (later than water and *myo*-inositol) and comprised 12 or 23% total activity in the caudal lumen and 13% in the corpus. The metabolite was not identified.

Transport of inositol from the bath into the lumen of the epididymis

Although the movement of tracer to the lumen was reduced when inositol concentrations in the bathing fluid were raised 200-fold (Text-fig. 2), the net flux of inositol to the lumen was increased, but by a smaller margin: 57-fold in the cauda and 87-fold in the corpus (Table 1). Total secretion rates were not significantly different in the corpus and cauda and were not directly related to length of the tubule. Secretion per unit length in the corpus epididymidis significantly exceeded that by the cauda in the presence of 10 mM-inositol ($P < 0.002$). Omitting glucose from the bathing fluid or adding inositol to the fluid perfusing the lumen did not significantly alter the total amount of inositol transported in 3 h (Table 1).

Table 1. Transport of *myo*-inositol from bath medium to the rat epididymal lumen during perfusion *in vitro*

In bath fluid		In lumen	Total transport			
Inositol (mM)	Glucose (mM)		nmol/3 h		nmol/3 h/cm

10.0	5.0	0	114 ± 15 (6)	143 ± 15 (6)	6.60 ± 1.14 (6)	14.92 ± 1.44 (6)
0.05	0	0	1.56 ± 0.28 (4)	—	0.115 ± 0.018 (4)	—
0.05	0	30	1.39 ± 0.30 (5)	—	0.084 ± 0.021 (5)	—

Values are mean $\pm$ s.e.m. for the no. of experiments in parentheses.

Transport of glucose from the bath to the lumen of the epididymis

When glucose concentrations in the bath were increased 11 000 times from tracer levels to 500 μM , the flux into the lumen increased by a similar amount: 9700-fold in the cauda and 8900-fold in the corpus. Raising the concentration a further 10-fold also increased transport to the lumen 10-fold in the cauda and 12-fold in the corpus (Table 2). Raising glucose concentrations in the lumen did

Table 2. Transport of glucose from bath medium to the rat epididymal lumen during perfusion *in vitro*

In bath Glucose (mM)	In lumen Glucose (mM)	Total transport			
		nmol/3 h		nmol/3 h/cm

not significantly increase transport to the lumen and there were no significant differences in secretion between corpus and cauda under similar conditions even when length was taken into account (Table 2).

Total secretion of unlabelled inositol and glucose into the lumen of the cauda epididymidis

In these experiments the tubules perfused were 17.9 ± 1.1 cm long. Inositol detected by g.l.c. appeared in the first samples of luminal fluid in all 12 experiments in which inflowing perfusion fluid was shown to be free of inositol. Its concentration did not decline during 3 h (data not shown), and the mean values from 3-h samples obtained from each epididymis are given in Table 3. These total secretion rates are from 20 to 36 times higher than the rates of transport from the bath (Table 1) and secretion was not consistently reduced when glucose or inositol were omitted from the bath. The mean ± s.e.m. concentration of inositol (300 ± 27 μM, $n = 28$) was 6 times greater than that present in the bathing fluid.

Glucose only appeared in luminal fluid when it was present in the bathing medium. Its mean ± s.e.m. concentration (64 ± 17 μM, $n = 12$) was only 1.3% of that in the bath and secretion rates, 11.55 ± 3.79 nmol/3 h or 0.81 ± 0.31 nmol/3 h/cm, were about 7% of those estimated to be transported from the bath (Table 2).

Table 3. Secretion of *myo*-inositol into the lumen of the rat epididymal lumen during perfusion *in vitro*

In bath fluid		Luminal perfusate		
Inositol (μM)	Glucose (mM)	Concentration (μM)	Secretion	
			nmol/3 h	nmol/3 h/cm
50	5	352 ± 69	66.6 ± 13.1	4.14 ± 0.82
50	0	221 ± 36	38.0 ± 6.0	2.29 ± 0.33
0	0	384 ± 36	70.0 ± 5.2	3.51 ± 0.42

Values are mean ± s.e.m. for 4 experiments.

Discussion

The epididymal preparation described here, where the environment on the two sides of the epithelium can be controlled, can be used to examine metabolism and directional transport across epididymal cells whose polarity in the epithelium is maintained. Inulin is an established marker that does not cross the rat blood–epididymal barrier (Cooper & Waites, 1979; Hinton & Howards,

1981; Hoffer & Hinton, 1984), so its low movement to the lumen, even when the cauda tubule was unravelled, indicates that there was not gross damage to the tubule during manipulation, and that maintaining the normal tubule configuration did not limit access of [^3H]inulin to the epithelium. That activity in the lumen of the corpus epididymidis was greater in the unravelled than the undissected tubules, suggests that focal damage can occur during preparation of a tubule that is less protected than the cauda by peritubular muscle (Reid & Cleland, 1957). Leakage to the extent observed may severely compromise estimates of water resorption made *in vitro* using inulin as a volume marker (Wong *et al.*, 1980; Cooper, Yeung & Wu, 1985). An alternative explanation for the increased entry of [^3H]inulin into unravelled tubules, that unravelling the tubules exposes them more to the bathing fluid, is not supported by three lines of evidence. Firstly, the mid-corpus region is only two tubules thick, so at least one side of each coil would be exposed to the medium. Secondly, the entry of tracer should be less rapid than in unravelled tubules and should continue until it reaches the plateau expected in the more accessible tissue and neither finding is supported by the data. Thirdly, access of tracer to the base of the epithelium is not limited because inositol and glucose entered the lumen to greater extents, and the extent and rate of movement of the former were similar to those obtained from an *in-vivo* preparation (Cooper, 1982) in which the excellent microvasculature of the epididymis (Kormano, 1968; Suzuki, 1982) is preserved.

The slowly rising activity of [^3H]inositol in the cauda lumen during perfusion suggests slow equilibration of tracer with a large pool of inositol as concluded from *in-vivo* experiments (Cooper, 1982). For the first time, data are presented for the corpus epididymidis in which luminal radioactivity from bath [^3H]inositol reached a plateau. Since the failure to reach a plateau in the cauda cannot be explained by its longer time for turnover of the luminal volume (25 min) compared to the corpus (6 min), and assuming equal densities of pumps in the 2 regions, the data suggest that tissue pools of inositol were less in the corpus than in the cauda, as are concentrations in the lumen (Hinton *et al.*, 1980).

In both regions the transport of [^3H]inositol occurred against a concentration gradient and was reduced when bath concentrations of inositol were raised, indicating the presence of membrane carriers, most probably associated with active pumps in the basal part of the epithelium. Increasing plasma concentrations of inositol similarly reduced transfer of circulating [^3H]inositol to the rat caput epididymal lumen (Hinton & Howards, 1982). Transport of [^3H]inositol in the cauda was not altered when glucose was removed from the bath, so carriers are likely to be specific for inositol and energy for the pump is not derived solely from extratubular glucose.

The extent of transfer in [^3H]inositol could provide at most a luminal concentration of $12.5\text{ }\mu\text{M}$, and although specific activity measurements were not made on individual samples, an estimate calculated from the relative concentrations of labelled and unlabelled inositol in the caudal lumen and bath at the end of perfusion is that luminal activity is 4% of that in the bath, close to that measured *in vivo* (3%: Cooper, 1982). The rate of inositol transport from the bath was indeed insufficient to account for the total secreted inositol measured by g.l.c., confirming the presence of large amounts of unlabelled inositol in the tissue. The *in-vitro* preparation can be used to locate the source of this inositol. The continued secretion of inositol when no glucose or inositol were provided in the bathing medium confirms the insignificant contribution of extratubular inositol, as inferred above, and rules out bath glucose as an immediate precursor. However, it is not possible to decide whether epithelial inositol arises from endogenous pools or by synthesis. In the absence of synthesis it can be calculated from histological measurements (Reid & Cleland, 1957) that an epithelial cell concentration of 17 mM would have to be depleted over 3 h to sustain the secretion rate observed during that time. The highest concentration, if diffusion were to account for movement from cell to lumen, would be that found in the lumen *in vivo* ($30\text{--}50\text{ mM}$: Hinton *et al.*, 1980; Cooper, 1982). Neither of these concentrations are likely to support the constant secretion observed in this study, and this argues for the biosynthesis of secreted inositol or intracellular concentrations in excess of 50 mM .

The presence of metabolites of glucose in the lumen, but not bath, indicated that the tissue supported metabolism, but in the present study no conversion to inositol was demonstrated. In other studies there was also no synthesis of inositol from glucose (Eisenberg & Bolden, 1964) or glucose 6-phosphate (W. C. L. Ford, personal communication) in epididymal homogenates. The activity of inositol synthase reported by Robinson & Fritz (1979) exceeds the activity of phosphoglucose isomerase 12-fold (Brooks, 1976a), using the epididymal protein content given by Brooks (1976b), so loss of tritium from the C₂-position of glucose 6-phosphate during glycolysis (Hammerstedt, 1975) should be minimal, although the conflicting reports on the activity of the relevant enzymes in rat epididymal tissue (Robinson & Fritz, 1979; Maeda & Eisenberg, 1980; Hasegawa & Eisenberg, 1981) need clarification and bear directly on the results of this study. The observations may also relate to the presence of endogenous pools of metabolites which were not equilibrated during the experiments, although work on tissue slices indicates that intracellular glucose is very low in glucose-containing medium (Brooks, 1979). Alternatively, the immediate precursor, glucose 6-phosphate (Eisenberg, 1967), may be in high concentration or compartmentalized. This precursor may also arise from epididymal glycogen, which can spare the utilization of glucose in tissue slices and provide lactate in the absence of glucose (Brooks, 1978). In support of this, the total activity of phosphorylase exceeds that of hexokinase (Brooks, 1976a), and intracellular glycogen is lost after castration (Cavazos, 1958) when inositol secretion is reduced (Pholpramool, White & Setchell, 1982). On the other hand, the conversion of inositol to phosphatidylinositol by caudal tissue and epithelium from the vas deferens *in vitro* (Voglmayr, 1974) reveals phospholipid as a possible alternative store of inositol.

Data on glucose movement across the epithelium were also obtained from these experiments. The absolute concentration of glucose in the lumen was much lower than that found *in vivo* (Cooper & Waites, 1979; Cooper, 1982) when blood levels were higher than the bath levels in the present studies. The bath was shown to be the sole source of luminal glucose and transport into the lumen was linearly related to concentration in the bath suggesting a diffusion process. Taking into consideration leakage and metabolism, the specific movement of labelled glucose to the lumen was about 9% that of the bath amount, a little above the value obtained *in vivo* (1–7%) for which the similar entry to the lumen of radioactivity arising from [¹⁴C]glucose and the non-metabolizable [³H]3-*O*-methylglucose suggested little metabolism of glucose in the epididymis of a different strain of rats (Cooper & Waites, 1979). The discrepancy between rates of secretion and transport of glucose in the present study may reflect inadequate separation of secreted metabolites from glucose.

The greater entry of tracer to the lumen of the cauda when glucose concentrations in the bath were reduced provides further evidence for the presence of carriers for facilitated diffusion in the basal membrane deduced from work on tissue slices (Brooks, 1978, 1979) and the reduced movement of circulating [³H]-3-*O*-methylglucose to caput epididymal fluid when blood glucose was raised (Hinton & Howards, 1982). Equally, the increased luminal movement of tracer, when the normal concentration gradient of glucose across the epithelium was reversed, can be explained by exchange-diffusion, whereby flux by mobile carriers in the apical membrane is increased by movement of sugar from the lumen into the cell. Glucose, unlike inositol, is removed when perfused through the lumen *in vivo* (Cooper, 1982).

The results suggest that carriers facilitate the diffusion of glucose from the bath fluid to the epididymal lumen across both cell membranes of epididymal epithelial cells, whereas inositol is pumped against a concentration gradient into the cell and secretion into the lumen is augmented by synthesis or release from an unidentified source.

We thank the W.H.O. Special Programme of Research in Human Reproduction and the State Family Planning Commission of China for making this research possible and Xing Zhijun and Mrs B. Parker for typing the manuscript. T.G.C. was a Consultant for U.N. project HRP/CPR/80/P07.
