Summary. The administration of oestrogen results in increased arterial blood flow in all mammalian species studied to date, but its mechanism of action has not been elucidated. Because an interval of 30–60 min is observed between oestrogen injection and uterine hyperaemia, it has been suggested that a vasoactive intermediate is involved and recent evidence suggests that catechol oestrogens are the vasoactive oestrogen intermediates. Uterine peroxidase catalyses the conversion of oestrogens to their catechol forms and thus may play an important role in oestrogen-induced uterine hyperaemia. The present studies evaluated the time course and dose–response effects of oestrogen on uterine peroxidase activity and related these to changes in uterine blood volume, an index of uterine hyperaemia in immature rats. These data demonstrated that the minimal effective hyperaemic dose of oestradiol also increased \((P < 0.05)\) uterine peroxidase activity. The oestradiol-induced increase in uterine peroxidase activity preceded significant increases in uterine blood volume \((1\ h\ versus\ 2\ h,\ respectively)\). These data are consistent with a role for peroxidase-mediated conversion of oestradiol to catechol oestradiol in facilitating uterine hyperaemia in rats.

Keywords: peroxidase; uterus; oestrogen; hyperaemia; rat

Introduction

Exposure of rat uterine tissue to exogenous oestrogen results in a marked increase in peroxidase activity \((\text{Lucas et al., 1955; Klebanoff, 1965; Jellinck & Lyttle, 1972; Anderson et al., 1975; Lyttle & DeSombre, 1977})\). Oestrogen-induced peroxidase activity of uterine tissues is mainly associated with subcellular microsomal particles \((\text{Lyttle & Jellinck, 1976; Hosoya & Saito, 1981})\). However, uterine fluid of oestrogen-primed rats also contains a soluble peroxidase \((\text{Klebanoff & Smith, 1970; Hosoya & Saito, 1981})\). Others have noted that a portion of eosinophil-stimulated uterine peroxidase activity occurs in the soluble fraction \((\text{Lyttle et al., 1989})\). Peroxidases catalyse the conversion of oestrogens to their catechol forms \((\text{Jellinck et al., 1985; Mondschein et al., 1986; Ball & Knuppen, 1990})\). Catechol oestrogens may be mediators of oestrogen-induced uterine hyperaemia \((\text{Van Orden et al., 1986; Ford, 1989; Rosazza et al., 1989})\). Thus, peroxidases may play an important role in the early vascular response to oestrogen.

Although peroxidase is a major oestrogen-regulated secretory protein of uterine epithelium \((\text{Jellinck & Newcombe, 1980})\), peroxidase activity has never been detected in uterine extracts earlier than 4 h after oestrogen exposure \((\text{Lyttle & DeSombre, 1977})\). In these reports, guaiacol was used to measure peroxidase activity; the poor sensitivity of this reagent in peroxidase assays probably precluded earlier detection of increased enzyme titres.

The present study uses the much more sensitive, ortho-phenylenediamine assay \((\text{Gallati & Brodbeck, 1982})\) to evaluate peroxidase activities in extracts of uteri taken from immature rats given
low doses of oestradiol and to determine whether peroxidase activity is related to the extent of uterine hyperaemia. In addition, we report a substantial quantity of oestrogen-dependent peroxidase activity in the soluble fraction of uterine homogenates.

Materials and Methods

Animals and treatments

Immature female Sprague–Dawley rats weighing 35–45 g were obtained from Harlan Laboratories (Madison, WI, USA) at 21 days of age and used in all experiments. Thirty-eight rats were assigned to the dose–response experiment, 36 rats were used for the time course experiment and 35 rats were used for a third experiment designed to study the distribution of uterine peroxidase activity at 2 h and 20 h after oestradiol.

A stock solution of oestradiol (Sigma Chemical, St Louis, Mo, USA) was prepared in 95% ethanol (1 mg ml⁻¹). Immediately before the dose response study, appropriate amounts of this stock solution were diluted with phosphate-buffered saline (PBS), pH 7.4, to make solutions for intravenous injection. The vehicle control consisted of PBS containing 0.1% ethanol. Each rat was weighed, then lightly anaesthetized with ether. The deep femoral vein was exposed and the selected dose of oestradiol or the vehicle was administered into the vein in a volume of 0.1 ml per 40 g body weight. The wound was closed with a wound clip and the animal allowed to regain consciousness. In the time course experiment, subcutaneous injections were used and the vehicle control consisted of 50% ethanol. A dose of 100 μg kg⁻¹ body weight was used for subcutaneous injections to assure delivery of at least 1 μg oestradiol kg⁻¹ body weight to the bloodstream. Intravenous administration of oestradiol in the dose–response experiment was chosen to assure consistent delivery of the oestrogen doses, whereas subcutaneous administration was chosen for the time course experiment to avoid the known effects of stress on delaying uterine hyperaemia.

Determination of uterine blood volume

In the dose–response experiment, uterine blood volume was determined 2 h after oestrogen injection, whereas in the time course experiment uterine blood volume was determined 1, 2 and 3 h after oestrogen injection. All animals were lightly anaesthetized with ether and a skin incision was made to expose the deep femoral vein. Each rat was given 10 μCi ¹²⁵I-labelled human serum albumin (in a volume of 0.1 ml) into the deep femoral vein using a 1 ml syringe and a 30 gauge needle. After equilibration for 5 min, the rats had regained consciousness and were killed by cervical dislocation. An abdominal incision was made and blood was obtained from the descending aorta. Aliquots of 100 μl were taken for measurement of radioactivity in a scintillation counter. The uterus and attached parametrium were excised and blotted to remove adherent blood from the surface. The tissue was weighed, then placed in 1 ml cold saline for measurement of radioactivity. The tissue was then frozen in liquid nitrogen for subsequent determination of peroxidase activity. The uterine blood volume was calculated using the formula:

\[ \text{μl blood g}^{-1} \text{tissue} = \frac{\text{c.p.m. g}^{-1} \text{ tissue}}{\text{c.p.m. in 1000 μl blood}} \]

Extraction of uterine peroxidase

Uterine horns from individual rats were frozen in liquid nitrogen and pulverized to a fine powder and subsequently homogenized in 1 ml of ice-cold Tris-HCl (pH 7.2) using a Polytron homogenizer PT 10/35 fitted with a PTA 7 generator (Brinkmann Instruments, Inc., Westbury, NY, USA). Homogenates were centrifuged (Beckman, Model L7-55R) at 40 000 g for 30 min at 4°C; the 40 000 g supernatant represented the soluble fraction. Pellets were rehomogenized in 1 ml ice-cold Tris-HCl (pH 7.2) containing 0.5 mol CaCl₂ 1⁻¹ to solubilize the peroxidase present in the particulate fraction and centrifuged at 100 000 g for 30 min at 4°C. The 100 000 g supernatant represented the Ca²⁺-extracted fraction.

Ortho-phenylenediamine assay of peroxidase activity

Peroxidase activity was determined by using the substrates H₂O₂ and o-phenylenediamine (Gallati & Brodbeck, 1982). The reaction mixture (1 ml) contained 650 μl of 154 mmol sodium citrate 1⁻¹ buffer, pH 5.0, 200 μl o-phenylenediamine solution (75 mmol 1⁻¹), 50 μl H₂O₂ (100 mmol 1⁻¹) and 100 μl of uterine enzyme extract. Soluble and Ca²⁺-extracted fractions were adjusted to 0.25 mol CaCl₂ 1⁻¹ immediately before assay. Higher concentrations of CaCl₂ reduced the colour intensity of the reaction. It was necessary to prepare 0.75 mmol o-phenylenediamine 1⁻¹ solutions in light-protected vials by adding o-phenylenediamine dihydrochloride tablets (Sigma Chemical Co., St Louis, MO, USA) to HPLC-grade water and to use the solution within 5 min of preparation. Reaction mixtures were vortexed and incubated at 25°C for 30 min and the reaction was stopped by the addition of 1 ml of 2M HCl. The absorbance was then determined at 496 nm using a DU-64 spectrophotometer (Beckman Instruments, Fullerton, CA, USA) and the
enzyme activity determined from a standard curve obtained with horseradish peroxidase. The tissue extract prepared from each rat uterus was assayed in duplicate at three dilutions. A laboratory extract pool was also assayed with each experiment to assess interassay reproducibility and parallelism to the horseradish peroxidase standard (Fig. 1). Results are expressed as pg horseradish peroxidase equivalents per mg of uterine tissue wet weight.

**Fig. 1.** Linearity of the o-phenylenediamine assay comparing five dilutions of horseradish peroxidase with dilutions of tissue extract.

**Statistical analyses**

Regression analysis was used to determine the dose–response relationship between oestradiol and uterine blood volume and between oestradiol and peroxidase. Analysis of variance was used to test which doses had associated mean responses that differed from one another.

**Results**

The lowest dose of oestradiol administered (0.5 μg kg⁻¹ body weight) produced a significant ($P < 0.05$) increase in uterine blood volume (Fig. 2); 1 μg kg⁻¹ body weight produced a greater ($P < 0.05$) increase in uterine blood volume than the 0.5 μg kg⁻¹ body weight dose but higher doses of oestradiol (up to 100 μg kg⁻¹ body weight) failed to produce any greater increase in uterine blood volume. Uterine blood volume was not altered in animals injected with vehicle (data not shown). Uterine blood volume remained unchanged for 1 h after oestradiol injection and then increased ($P < 0.01$) at 2 and 3 h (Fig. 3).

As was the case for the uterine blood volume responses, the lowest dose of oestradiol that produced a significant ($P < 0.05$) increase in uterine peroxidase activity in the Ca²⁺-extracted fraction was 0.5 μg kg⁻¹ (Fig. 4). Uterine peroxidase activities at doses of oestradiol from 0.5–5 μg kg⁻¹ body weight were positively correlated ($P < 0.05$, $r = 0.79$) with the uterine blood volume.

Uterine peroxidase induction was observed during the time course of uterine hyperaemia (Fig. 5). Peroxidase activity (11.5 ± 1.8 pg mg⁻¹) was detected in the CaCl₂ extract of individual uteri harvested from untreated control animals. Furthermore, oestrogen treatment produced a significant ($P < 0.05$) increase in enzyme activity as early as 1 h with no further increase observed at 2 and 3 h.

Oestradiol treatment (100 μg kg⁻¹ body weight) not only increased the Ca²⁺-extracted peroxidase activity but also increased the level of soluble peroxidase activity (Fig. 6). The amount of peroxidase activity in the soluble fraction was two to three times greater than that observed in the Ca²⁺-extracted fraction. At 20 h, oestrogen exposure increased the Ca²⁺-extracted peroxidase
Fig. 2. Uterine blood volume response to vehicle (n = 6) or the indicated quantities of oestradiol (n = 4–6). Uterine blood volume was measured using ¹²⁵I-labelled albumin 2 h after i.v. administration to immature rats. a,b,c Means (±SEM) with different letters are significantly different (P < 0.05).

Fig. 3. Uterine blood volume response to vehicle (■) or 100 µg kg⁻¹ body weight oestradiol (□) at three time points after s.c. administration to immature rats (six animals per time point). Within a treatment, means (±SEM) with different letters (a,b) are significantly different (P < 0.01).

activity in comparison with the 2 h exposure. During the same time, levels of soluble peroxidase remained constant.

Discussion

Oestrogen administration has previously been shown to increase activity of peroxidase in the uterus considerably with maximal activity appearing 20–24 h after a single injection (DeSombre, 1984). This study showed for the first time that oestrogen also increases uterine peroxidase activity before this, within 1–3 h after injection. These data also demonstrate that the lowest dose of oestrogen that increases uterine peroxidase (0.5 µg kg⁻¹ body weight) is one-fifth the effective dose reported by others (Lyttle & DeSombre, 1977). The picogram range of sensitivity observed with the o-phenylenediamine assay allowed detection of subtle changes in enzyme activity that would not be possible with the standard guaiacol substrate assay for peroxidase, which requires 100 ng of enzyme for oxidation.
**Fig. 4.** Peroxidase activity determined by o-phenylenediamine in calcium chloride extracts of individual uteri of immature rats injected (i.v.) with vehicle (n = 6) or the indicated quantity of oestradiol (n = 6). a,b,c Means (±SEM) with different letters are significantly different (P < 0.05).

**Fig. 5.** Peroxidase activity determined by o-phenylenediamine in calcium chloride extracts of individual uteri of immature rats killed at three time points (six animals per time point) after s.c. administration of 100 μg kg⁻¹ body weight oestradiol. Control represents average peroxidase activity obtained from 18 animals (six per time point) after vehicle injection. a,b Means (±SEM) with different letters are significantly different (P < 0.05).

The dose–response study showed that uterine peroxidase activity is positively correlated with the early vascular response to oestradiol administration, namely, uterine hyperaemia. It appears that the dose–response range is very narrow 2 h after oestrogen administration when uterine hyperaemia is the dominant oestrogen response. This observation, together with the finding that increases in uterine peroxidase precede increases in uterine blood volume (Figs 3 and 5), suggests that a change in peroxidase activity is involved in the initiation of uterine vasodilation and that, once underway, enzyme activity does not continue to increase during the hyperaemic response.
The biological importance of an early rise in peroxidase activity after oestrogen exposure may be a critical link in the development of uterine hyperaemia. Catechol oestrogens not only dilate the uterine artery in vivo but are also the only oestrogen compounds that are effective in vitro as well (Stice et al., 1987). Thus it has been suggested that catechol oestrogens may be the mediators of the vascular effects of oestrogen. We showed that the metabolism of oestrogens by uterine peroxidase yields catechol oestrogens (Rosazza et al., 1989) and that uterine arteries can synthesize catechol oestrogens from the parent oestrogens (Van Orden et al., 1983). In addition, these hydroxylated oestrogens may have a negative feedback effect on peroxidase by behaving like suicide inhibitors of the enzyme that synthesizes them (Rosazza et al., 1989). Oestrogen has been reported to inactivate uterine peroxidase; this suggests a role for this enzyme in many diverse events such as cell detoxification, bactericidal action and hormone recycling (Klebanoff, 1965; Brokelman, 1969; Jellinck et al., 1979). From previous and present data, a sequence of events after administration of oestrogen may be: increased peroxidase activity, hydroxylation of oestrogen, vasodilation and subsequent inactivation of the synthesizing enzyme, peroxidase.

The origin of the uterine peroxidase that is increased soon after administration of low dose oestrogen is unknown. In studies using long-term exposure to oestrogen (>24 h), it has been shown that peroxidase may come from two distinct sources: endogenous uterine tissue peroxidase and eosinophil-derived peroxidase (Tchernitchin et al., 1974; King et al., 1981). Although Olsen & Little (1982) suggest that these two enzymes are identical (on the basis of range of similar properties), others have presented cytochemical and biochemical evidence that distinguishes the endogenous and the exogenous or eosinophil peroxidases. Anderson et al. (1986) noted that as many as 15 peroxidase isoforms are expressed at successive stages after stimulation of the uterus with oestrogen.

Since the immature rat has a very poorly developed uterine epithelium, it appears more likely that the peroxidase activity measured very soon after exposure to a low dose of oestrogen could be from eosinophils. Lyttle's group (Lee et al., 1989) has recently proposed that oestrogen regulation of eosinophil peroxidase occurs by a uterine chemotactic factor (ECF-U), the synthesis of which is mediated by the oestriadiol receptor. Although they report that the maximum increase was not observed until 24 h, there was a significant increase in ECF-U activity 3 h after injection of 1 μg oestriadiol. Peroxidase activity, as measured by the o-phenylenediamine assay in the current study, was significantly increased 1 h after oestrogen injection (Fig. 5); this may indicate that the very early
response (1–3 h) either precedes the elaboration of the chemotactic protein, or that the detection limits of the chemotaxis assay prevent the measurement of earlier increases in activity. Eosinophils have been shown to increase in number within 5 min of oestrogen administration (Tchernitchin et al., 1974) but the number of cells required to provide a measurable quantity of peroxidase will depend on the sensitivity of the enzyme assay used.

The administration of oestrogen to immature rats resulted in unexpectedly high peroxidase activity (>200 pg mg⁻¹ protein) in the soluble fraction of uterine homogenates (Fig. 6). Others, using the guaiacol assay, have shown little (4-3%) or no activity in the uterine soluble fraction (Hosoya & Saito, 1981) or the hypotonic supernatant fraction (Lyttle & DeSombre, 1977) obtained from oestrogen-treated rats. The differences between these observations and those reported in the present study may be explained by detection limits (o-phenylenediamine assay is 1000-fold more sensitive than guaiacol) or substrate specificities or by both. Peroxidase activity was also present in a soluble fraction from uterine tissue when an alternative substrate, 4-aminoantipyrine, was used as the hydrogen donor (authors’ unpublished data). Lymphatic fluid from the uterus of pregnant pigs, assayed using o-phenylenediamine, was found to contain large quantities (>5 ng ml⁻¹) of peroxidase activity (authors’ unpublished data). Hosoya & Saito (1981) reported large quantities of a uterine fluid peroxidase that has a molecular weight twice that of uterine tissue peroxidase, a different CM–cellulose chromatography elution profile and electrophoretic properties that are rather different from those of uterine tissue peroxidase. Furthermore, Gabriel et al. (1986) have combined cytochemical, immunocytochemical and autoradiographic studies to show that oestrogen induces the synthesis and secretion of numerous peroxidase isozymes found in the uterine fluid.

In conclusion, quantitative measurements of uterine blood volume and uterine peroxidase activity using the sensitive o-phenylenediamine assay provide evidence, for the first time, that levels of peroxidase are directly correlated with the extent of uterine hyperaemia, the early vasocul response to exposure to oestrogen. Activity of soluble peroxidase is also high in the uterus during oestrogen hyperaemia and this warrants further study concerning its characteristics and the potential for conversion of oestrogens to vasoactive catechol oestrogen.

The authors thank E. Rus for technical assistance and L. Lammer for preparation of the manuscript.
