The absence of outer dynein arms in the sperm flagellum induces an abnormal movement pattern associated with male infertility. These spermatozoa can decondense in zona-free hamster oocytes but result in a very low fertilization rate in in vitro fertilization. We hypothesized that subzonal insemination could help achieve fertilization and pregnancy. A randomized prospective trial (five couples, five cycles) comparing subzonal insemination (n = 31 oocytes) and routine IVF (n = 23 oocytes) was carried out. Oocytes were microinjected with 8.5 ± 3.6 spermatozoa. In a second series (nine cycles), all the oocytes were microinjected with 10.5 ± 4.3 spermatozoa. In the randomized series, the fertilization rate was 16.1% without polyploidy, whereas no fertilization was obtained after control IVF insemination. In the second series involving nine couples, six of whom were included in the first series, the fertilization rate increased to 57.8% with a 27.8% polyspermic rate. Eighty-eight per cent of the zygotes cleaved normally (29 out of 33). A total of 11 embryo transfers resulted in three pregnancies, one of which terminated one month later, a second being ongoing and the third delivering a healthy girl. A 21.4% pregnancy rate per cycle, with a 37.5% pregnancy rate per couple, justifies the use of subzonal insemination to treat this particular flagellar dyskinesia.

Introduction

Various axonomal defects have been described in the spermatozoa of infertile men. Most defects are responsible for flagellar immotility (Afzelius and Eliasson, 1979; Bacetti et al., 1979; Escalier and David, 1984; Escudier et al., 1990). In some cases, the absence of the outer dynein arms is the only detectable defect. The spermatozoa are motile, but there is a flagellar dyskinesia that is associated with male sterility: decreased sperm movement is observed. The diagnosis is based on finding less than three outer arms on all the electron micrograph axoneme cross-sections of the same sample. The movement pattern of these spermatozoa is characteristic. The shape of their principal flagellar curvature is similar to that of normal spermatozoa but their curvilinear velocity, straightline velocity and flagellar beat frequency are approximately half those of control values (Jouannet et al., 1983). These spermatozoa can migrate in cervical mucus but their penetration is partially or completely impaired (Jouannet et al., 1983). As a consequence, failure to ascend the female reproductive tract results in infertility as has been shown for other abnormal sperm movements that impede interaction between spermatozoa and cervical mucus (Aitken et al., 1986).

Microfertilization techniques may be a useful treatment in cases of male infertility (Ng et al., 1988; Garrisi et al., 1990; Fishel et al., 1990). Since the flagellar dyskinesia can impair the interaction between spermatozoa and zona pellucida, we hypothesized that subzonal insemination could help in achieving fertilization and pregnancy for patients whose infertility is related to this particular sperm pathology. The local Ethical Committee gave its approval. In a first series of trials, we ran a randomized clinical trial comparing a routine IVF procedure with subzonal insemination (n = 5 cycles for five different patients). In a second series of trials, three new patients were included in the programme, and six repeated attempts were performed for patients who were already unsuccessfully involved in the first series. In view of the encouraging results of the first series, all the oocytes of the second series were microinjected with a greater number of spermatozoa without any randomization.

Patients and Methods

Selection of patients

Eight couples with primary infertility for a mean duration of 7 years (range 3–12) were included in the study. The men

Received 6 May 1992.
were 31.5 ± 1.5 years old (range 29–34) and the women 30.7 ± 2.1 years old (range 27–34). Two couples had two previous IVF attempts each (38 oocytes) without any fertilization. Sperm counts and motility were determined by classical methods. The sperm analysis included a characterization of the sperm movement pattern using a computerized analysing system (M 2030; Hamilton Thorn, IMV France), an in vitro cervical mucus penetration and immunobead test. The sperm morphology was assessed on a smear stained with Schorr and haematoxylin according to the classification of David et al. (1975). The structural defect was suspected for these patients because their sperm exhibited a limited cervical mucus penetration test in spite of a normal or subnormal percentage of motile spermatozoa and an absence of anti-sperm antibodies. The study of their movement pattern confirmed the flagellar dyskinesia. The diagnosis was finally confirmed by examination of spermatozoa by electron microscopy, which revealed that spermatozoa from seven patients had a complete absence of outer dynein arms and 60% of spermatozoa from the last patient had this abnormality (A2) (Fig. 1). The sperm analysis was completed by a test of selection by centrifugation and centrifugation through a simplified Percoll gradient (95%, 47.5%) (Pharmacia, France) and a study of the percentage of motile forms in B2 Menezzo’s medium (Bio Mérieux, France) after incubation for 24 h at 20°C (Survival Test). The sperm fusiogenic function was evaluated by a zona-free hamster oocyte penetration assay before including the patients in the programme. This test was carried out by incubating thirty eggs in a sperm suspension containing 2.5 × 10⁶ motile spermatozoa ml⁻¹ for 3 h. The spermatozoa had been collected the day before the test and the motile spermatozoa selected by centrifugation through a two-density Percoll gradient (95 and 47.5%) and then incubated for 18 h in BWW medium (Biggers et al., 1971) at 18°C.

Oocyte preparation

Follicular stimulation protocols were performed with a combination of a GnRH analogue and human menopausal gonadotrophin. Ovulation was induced with 5000 iu of hCG and oocytes were harvested 36 h later using a transvaginal ultrasound-guided procedure (Frydman et al., 1988). The cumuli were washed and individually placed in 40 µl of B2 medium under equilibrated mineral oil. The cumulus cells were removed with 0.1% hyaluronidase (Type III, Sigma, St Louis, MO) in B2 medium and the eggs checked for their nuclear status on the basis of the presence or absence of the first polar body or of the germinal vesicle (Veeck, 1986).

In the first series of experiments, the microinjection technique was tested in a trial during which oocytes were randomly divided into two groups. Oocytes from the first group were inseminated by a routine IVF technique (n = 23), and the others had subzonal insemination (n = 31).

In the second series (n = 90), all the oocytes were microinjected. For both series, the procedure took place 6–8 h after egg retrieval, regardless of nuclear maturity unless oocytes still presented a germinal vesicle. In this latter case they were matured in vitro before insemination or subzonal insemination (7 of 147 oocytes).

Sperm microinjection

Microinjection was performed using two Narishige micromanipulators and an inverted Olympus IMT-2 microscope. Differential interference contrast optics were suitable for carrying out the procedure. Micropipettes were pulled on a vertical Narishige PB-7 puller (8 µm diameter), and holding pipettes were prepared on a De Fonbrune microforge (Alcatel, France). Subzonal insemination was performed in 3 µl of Heps-buffered B2 medium containing 0.1 mol sucrose 1⁻¹ at pH 7.4, under equilibrated mineral oil. The oocytes were transferred onto a glass depression slide, and a 3 µl of sperm suspension in B2 medium was placed on another slide. A few spermatozoa were aspirated into the microinjection pipette, flagellum first. The oocyte was then caught by the holding pipette and the zona pierced; spermatozoa were allowed to swim into the perivitelline space. Oocytes were then returned to the culture medium in an air:5% CO₂ incubator at 37°C. The total procedure took less than 5 min. The mean number of spermatozoa microinjected was 8.5 ± 3.6 in the first series and 10.5 ± 4.3 in the second (range 1–20).

Control IVF oocytes

Control oocytes were inseminated after the cumuli had been dispersed by 0.1% hyaluronidase in B2 medium. They were inseminated with 5000 motile spermatozoa in 40 µl B2 medium drops under mineral oil and kept in an air:5% CO₂ incubator at 37°C.

Embryos

The oocytes were checked 16–18 h after insemination or subzonal insemination for evidence of fertilization. Oocytes

Fig. 1. Electron micrographs of the principal piece of human sperm flagella (transverse sections): (a) Normal spermatozoon exhibiting outer dynein arms (arrowhead). (b) Spermatozoon without dynein arms (arrow) from a patient. Bars = 0.1 µm.
exhibiting two pronuclei were considered normally fertilized. An oocyte was considered unfertilized or polyspermic when no pronucleus or more than two pronuclei, respectively, were found. Diploid zygotes were kept in culture for a further 24 h. Regularly cleaved embryos only were transferred.

**Statistical analysis**

Groups of oocytes were compared by Chi squared tests. Differences were considered significant at $P < 0.05$. Regression and correlation coefficients were studied using the STATWORKS package.

**Results**

**Characteristics of individual patient's spermatozoa**

Except for patient A1, sperm counts were normal (Jouannet et al., 1988); the mean was $59.1 \times 10^6$ spermatozoa ml$^{-1}$ (range: $10-127 \times 10^6$). The percentage of motile spermatozoa was low for four patients (A1, A5, A7 and A8). The percentage of spermatozoa with normal morphology and the percentage with acrosome defects were comparable to those of a fertile population except for patients A5 and A7 who had an increased incidence of acrosome defects (41 and 40%, respectively). Patient A5 also presented a reduced percentage of oocytes with decondensed sperm heads in the zona-free hamster oocyte penetration test (9%), whereas the mean for all patients was $49.8 \pm 27.1$% (Table 1). All patients had positive survival tests and no anti-sperm antibodies. Analysis of sperm movement revealed the characteristic pattern of spermatozoa lacking outer dynein arms: reduced mean straight line velocity of $5.5 \pm 14.9 \mu m s^{-1}$ (range $7.8-21$) and normal mean lateral head displacement of $2.6 \pm 1.3 \mu m$ (range $0.8-3.7$).

Results of subzonal insemination

A total of 147 oocytes were retrieved in 14 cycles. Sixty-eight per cent were at metaphase II at the moment of insemination or subzonal insemination. One hundred and twenty-four were microinjected. Cellular damage occurred in three cases (2.5%).

In the randomized series, fertilization was obtained for three of the five couples by subzonal insemination (Table 2). Five oocytes out of 31 were fertilized (16.1%). Four eggs cleaved normally and one remained blocked at the pronucleus stage.

aSecond cycle for the same couple. bThird cycle for the same couple.

There was no polyplody among these eggs and no fertilization was obtained in the control IVF group (23 oocytes). Three embryo transfers were performed, with one embryo in two cases (patients A1 and A2) and two embryos in the other (patient A3). One pregnancy resulted from the transfer of an embryo but miscarried one month later (patient A2).

In the second series (subzonal insemination only; Table 3), 90 oocytes were microinjected with a greater number of spermatozoa. Fifty-two fertilized (57.8%), of which 25 were polyspermic; the diploid fertilization was obtained for only 30.0% of the microinjected eggs. Of these diploid zygotes, 87.8% cleaved normally. Fertilization was obtained in every case in this second series, including patient A4 who had failed to fertilize during the first series. The number of normal embryos obtained for patients who had repeated attempts was generally improved. All the patients had an embryo transfer: four of them with three embryos, and two with one and two embryos, respectively. Two pregnancies were obtained. One gave birth to a healthy baby girl (patient A6), and the other pregnancy is still ongoing (patient A7).

The nuclear status at the time of subzonal insemination was recorded for 80 oocytes. Among metaphase I oocytes (n = 59), 45.8% fertilized after subzonal insemination. This percentage dropped to 28.5% for metaphase II oocytes (n = 21), but this difference was not statistically significant (P > 0.05). No fertilization occurred when less than five spermatozoa were placed in the perivitelline space (Fig. 2). Thirty-seven per cent of the oocytes microinjected with five to nine spermatozoa fertilized with 16.7% rate of polyspermy. When more than ten and 15 spermatozoa were microinjected, the fertilization rates increased to 46.7 and 47.3%, respectively, with a moderate augmentation of the polyspermy rate (21%). A correlation coefficient of 0.81 was found between the fertilization rate for the first attempt of five patients (A1, A2, A3, A5 and A6) whose oocytes were microinjected with the same range number of spermatozoa (8.5 ± 3.6) and the percentage of hamster oocytes with decondensed sperm heads (P = 0.09). Furthermore, the number of spermatozoa that allows a diploid fertilization was different from one couple to another, but was remarkably constant for individual couples, from one egg to another and between repeated attempts.

**Discussion**

It would be reasonable to query the ethics of assisting fertilization in patients with spermatozoa that lack outer dynein arms considering the potential risk of transmitted disease. However, no connection between the absence of outer dynein arms and genetically transmitted disease has been established, and neither the men who donated spermatozoa, nor male relatives, nor offspring born five years ago after IVF presented with respiratory disease (Spira et al., 1986). Furthermore, no defects in respiratory ciliary cells were found in patients whose spermatozoa lacked outer dynein arms (Escudier et al., 1990). In sea urchins, it has been shown that the alpha-heavy chains of sperm flagellar and ciliary outer arm dyneins are different (Ogawa et al., 1990). It is possible that such a difference also exists in other species. The potential risk of transmitting respiratory diseases, therefore, seems low. However, patients were informed of this possibility, and their acceptance of a long-term follow-up of the children has been obtained.

We report a series of 14 attempts of subzonal insemination with spermatozoa lacking outer dynein arms, including a comparison between subzonal and routine IVF insemination in a prospective randomized clinical trial, yielding three pregnancies and the birth of one baby. Zona-free hamster eggs decondensed human immotile spermatozoa lacking both dynein arms, suggesting that fertilizing ability may be, at least partially, dissociated from the sperm movement pattern (Aitken et al., 1983). These spermatozoa can undergo normal acrosome reaction as seen by transmission electron microscopy (Aitken et al., 1983). Fertilization of three human oocytes by subzonal insemination of a single immotile spermatozoon has also been achieved (Bongso et al., 1989). The embryos obtained cleaved normally but their transfer did not result in pregnancy. Spermatozoa lacking only outer dynein arms can also decondense in zona-free hamster eggs, although the mean percentage of oocytes with swollen sperm heads is lower than that with normal control spermatozoa (Courtot et al., 1985). These data
demonstrate the ability of these spermatozoa to complete capacitation, to undergo acrosome reaction and to attach to the vitelline membrane and fuse with it (Courtot et al., 1985). Pregnancy with spermatozoa lacking outer dynein arms has been achieved. Spira et al. (1986) carried out an IVF programme of eight cycles for five couples presenting this sperm defect. Out of 36 oocytes, three were fertilized for one patient. The embryo transfer resulted in a twin pregnancy. The two girls are now five years old and appear normal. All these results demonstrate the low fertilization capability of spermatozoa lacking dynein arms but that when fertilization occurs normal embryos can be produced. We confirm the low fertilizing ability of spermatozoa lacking outer dynein arms when placed in contact with the zona pellucida of human oocytes; zygotes were not obtained after the routine IVF insemination of 23 control oocytes. The duration of the sterility of the couples, and the very low fertilization rate obtained by classic IVF procedures justify complementary techniques such as subzonal insemination. Indeed, the overall fertilization rate was 47.1% after subzonal insemination for 121 oocytes, with a 37.5% pregnancy rate per patient.

Few characteristics of spermatozoa lacking outer dynein arms seem to be important. In the first randomized series, the fertilization rate was relatively low (16.1%) and the rate of polyspermy was nil. In a similar study performed after IVF failure with structurally normal spermatozoa, microinjection of comparable numbers of spermatozoa under the zona pellucida almost doubled the fertilization rate (29.4%) and the polyspermy rate was very high (Wolf et al., 1992). This suggests that the fusiogenic capability of spermatozoa lacking outer dynein arms is decreased even when microinjected under the zona pellucida. These findings confirm the observations previously made with the hamster oocyte penetration test. This is why we decided to increase the number of microinjected spermatozoa to more than 10 in the second series. This resulted in an improvement in the fertilization rate (up to 57.8%) but with a polyspermy rate of 27.8%. However, the percentage of diploid zygotes was 30.0% of microinjected oocytes, which is a better result than in the first series. In every attempt of the second series, there was a minimum of one egg fertilized per couple and one embryo transfer, even for patient A4 who failed to achieve fertilization in the first cycle. The difference in the rate of polyspermy between the two series (nil for the first and 27.8% for the second) is surprising since the increase of the number of spermatozoa microinjected was relatively small. It suggests that the fertilization rate and the rate of polyspermy are not linearly related to the number of spermatozoa microinjected into the perivitelline space. The fertilization rate reached a plateau when more than ten spermatozoa were microinjected and data collected from more than 1000 oocytes after subzonal insemination (not shown) suggest that a threshold might exist.

To reduce polyspermy, it would be useful to have criteria that could predict the optimum number of spermatozoa to microinject. The correlation between the hamster egg penetration assays and the fertilization rate after zona drilling for patients who had previous unsuccessful IVF cycles has been studied but found not to be significant (Vazquez-Levin et al., 1990). We also failed to find any correlation when we performed subzonal insemination for patients with previous IVF failure (Wolf et al., 1992). This correlation coefficient for the five patients who had the same number range of spermatozoa microinjected almost reaches significance in spite of the small number of cases. It could probably serve as a guideline to determine prospectively the number of spermatozoa to microinject. This number would also probably depend upon the percentage of motile and acrosome-reacted spermatozoa present in the suspension after migration, as well as on oocyte quality. This hypothesis is under evaluation.

In conclusion, subzonal insemination appears to be a reliable technique for achieving fertilization and pregnancy in cases of infertility related to flagellar dyskinesia owing to the lack of outer dynein arms and should be preferred to IVF. The zona-free hamster egg penetration assay appears to be a good indicator of the number of spermatozoa to microinject, but this needs to be confirmed by a study involving larger numbers of patients.

This work has been supported by INSERM CFJ 8810 and Assistance publique 'Contrat de Recherche Clinique n° 910602'. Part of the results were presented at the 7th World Congress on In Vitro Fertilization and Assisted Procreation, Paris, July 1991.
