Role of platelet-derived growth factor in development of in vitro matured and in vitro fertilized bovine embryos

J. K. Thibodeaux, R. P. Del Vecchio* and W. Hansel†

Departments of Animal Science and Veterinary Science, LAES, LSU Agricultural Center, Louisiana State University, Baton Rouge, LA 70803, USA

This experiment was designed to determine whether the stimulatory effects of bovine oviductal epithelial cells (BOEC) on development of early bovine embryos are due to platelet-derived growth factor (PDGF). Four hundred and twenty five 8-cell bovine embryos derived from in vitro maturation and in vitro fertilization procedures were equally and randomly allotted to one of the following culture treatment groups: control medium alone (Menezo’s B2 medium; MB2), MB2 with 1 ng PDGF ml⁻¹ (PDGF), 1 ng PDGF ml⁻¹ and 10 μg anti-PDGF antibody ml⁻¹ (PDGF + Ab), BOEC or BOEC and 10 μg anti-PDGF antibody ml⁻¹ (BOEC + Ab). All embryos were cultured in 100 μl of serum-free MB2 medium supplemented with 2 mg fatty-acid-free bovine serum albumin ml⁻¹. Embryos for all treatment groups were incubated at 39°C and 5% CO₂ in humidified air in groups of five embryos per well in 96-well culture plates until 7 days after in vitro insemination. A higher proportion of embryos developed to > 8-cell and to the morula stage following culture with PDGF, BOEC or BOEC + Ab than with MB2 alone. Incubation of PDGF and BOEC-treated embryos with anti-PDGF reduced development to the morula and blastocyst stages. However, anti-PDGF did not completely inhibit blastocyst development when added to BOEC. In addition, embryos incubated with BOEC and anti-PDGF contained a reduced number of inner cell mass cells compared with embryos incubated with BOEC alone. These results indicate that PDGF provides a developmental stimulus similar to BOEC for bovine embryos at the fourth cell cycle. The addition of PDGF antibodies appears to reduce early embryo development by inhibiting PDGF action. However, BOEC may also produce factors other than PDGF that are beneficial to early bovine embryo development during in vitro culture.

Introduction

The development of embryo co-culture systems using various types of ‘helper cell’ has provided a more efficient means of maintaining embryos in vitro for extended periods with minimal reduction in viability (see review by Rexroad, 1989). Culture systems, such as uterine fibroblasts (Voelkel et al., 1985; Wiemer et al., 1988), and epithelial cells (Goodeaux et al., 1990), oviduct cells (Gandolfi and Moor, 1987; Rexroad and Powell, 1988; Ellington et al., 1989; Eyestone and First, 1989; McCaffery et al., 1991), trophoblastic vesicles (Camous et al., 1984; Heyman et al., 1987; Pool et al., 1988), granulosa cells (Fukuda et al., 1990; Zhang et al., 1992), chick embryo amnion (Blakewood et al., 1989; Blakewood et al., 1990) and conditioned medium (Eyestone and First, 1989; Eyestone et al., 1991; Pinyopummitr and Bavister, 1991), have allowed researchers to study embryonic development in farm animal species during prolonged in vitro culture. Although the beneficial effects of co-culture systems have been demonstrated by many different laboratories in recent years, the biochemical components and interactions between the developing embryo and cellular monolayers are not well understood.

Embryonic development consists of a series of events including cell proliferation and differentiation in which several growth factors appear to play key regulatory roles. It is possible that the embryotrophic effects of co-culture systems are mediated via the secretion of one or more growth factors. This suggestion is further strengthened by a recent report of the detection of platelet-derived growth factor (PDGF) in bovine oviductal secretions (Gandolfi et al., 1991). In addition, one research group (Larson et al., 1992) reported that the addition of 1 ng PDGF ml⁻¹ to the culture medium induced bovine embryos to develop beyond the 8- to 16-cell ‘block’ stage. Larson et al. (1992) noted that PDGF activated specific proto-oncogenes and reduced the duration of the fourth cell cycle. Other growth factors, such as fibroblast growth factor (bFGF) and transforming growth factor α (TGF-α), appear to play more significant roles at the fifth cell cycle (Larson et al., 1992). TGF-β may also act synergistically with epidermal growth factor (EGF) to increase the incidence of hatched blastocysts in bovine embryos matured and fertilized in vitro (Keefler, 1992).

The present experiment was designed to study the role of PDGF in early bovine embryo development and to test the hypothesis that all, or part, of the beneficial effects of co-culture...
of early bovine embryos with bovine oviductal epithelial cells (BOEC) is due to PDGF.

**Materials and Methods**

**Experimental embryos**

Bovine embryos were produced using modifications to procedures described by Thibodeaux et al. (1992) for in vitro maturation (IVM) and in vitro fertilization (IVF) of follicular oocytes. Ovaries used for harvesting cumulus-intact oocytes were obtained from a local abattoir and from an abattoir in South Carolina. Ovaries were packaged in thermal containers in phosphate-buffered saline (PBS; Gibco Laboratories, Grand Island, NY) and reached the laboratory 4–8 h after collection. Upon reaching the laboratory, oocytes were washed several times with fresh PBS containing antibiotics (100 units penicillin and 100 µg streptomycin ml⁻¹; Gibco). Oocytes were then aspirated from 2–6 mm follicles using a 20 gauge needle with a 10 ml syringe. Initially, cumulus-intact oocytes were matured for 22–24 h at 39°C and 5% CO₂ in humidified air in 4-well culture plates (Nuncclon, Naperville, IL) containing 500 µl of IVM medium overlaid with mineral oil (E. R. Squibb and Sons, Inc., Princeton, NJ). The IVM medium consisted of Tissue Culture Medium-199 (TCM-199; Gibco) supplemented with 10% heat-treated fetal bovine serum (FBS; Hyclone Laboratories, Logan, UT), antibiotics and hormones (0.01 IU purified bovine FSH and LH ml⁻¹; NOBL Laboratories, Sioux Center, IA).

After IVM, oocytes were washed twice with BO medium (Brackett and Oliphant, 1975) containing 20 mg BSA ml⁻¹ (Sigma Chemical Co., St Louis, MO) and transferred to 50 µl drops of BO medium containing BSA overlaid with mineral oil. For IVF, two straws of frozen–thawed semen from the same Holstein bull were washed twice in BO medium supplemented with 10 mmol caffeine sodium benzoate l⁻¹ (Sigma) (6 ml per wash) and exposed to 0.1 µmol Ca²⁺ ionophore A23187 l⁻¹ (Sigma) for 1 min. A 50 µl portion of sperm cells containing 1.5 × 10⁶ motile sperm cells ml⁻¹ was added to oocytes (15–20 oocytes per droplet) after exposure to Ca²⁺ ionophore and incubated for an additional 5–6 h at 39°C and 5% CO₂ in humidified air. After the insemination interval, oocytes were washed twice in TCM-199 with 10% FBS and antibiotics, then incubated for an additional 56–60 h at 39°C and 5% CO₂ in humidified air before allocation to treatment groups.

**Isolation and culture of oviduct cells**

Bovine oviducts were obtained at a local abattoir from animals in the early luteal stage of the oestrous cycle and transported to the laboratory on ice in Ca²⁺ - and Mg²⁺-free PBS (Sigma) supplemented with 200 units penicillin, 200 µg streptomycin and 0.25 µg amphotericin B ml⁻¹. Oviductal cells from both oviducts were stripped with fine forceps from the isthmus distal to the infundibulum as described by Thibodeaux et al. (1992) and resuspended in TCM-199 with 10% FBS and antibiotics. Oviductal cells were washed with fresh cell culture medium and portions of the cell suspension incubated in 96-well plates (100 µl suspension per well) at 39°C and 5% CO₂ in humidified air. Oviductal cells were used for embryo culture experiments upon reaching confluency, usually within 96 h of initial cell seeding.

**Embryo culture**

Early 8-cell stage bovine embryos were harvested from the initial culture (TCM-199 with 10% FBS and antibiotics) 56–60 h following IVF. The duration from insemination to harvesting embryos was based on the length of the first four cell cycles as previously reported (Barnes and Eyestone, 1990; Barnes and First, 1991). Larson (1991) indicated that the beneficial effects of PDGF on bovine embryo development occurred at the fourth cell cycle. Embryos were washed several times in serum-free Menezo’s B2 medium (MB2; Menezo et al., 1984; API Biomerieux, France) then equally and randomly allotted to one of five culture treatment groups as follows: control medium alone (MB2), MB2 with 1 ng PDGF ml⁻¹ (PDGF), 1 ng PDGF ml⁻¹ and 10 µg anti-PDGF antibody ml⁻¹ (PDGF + Ab), BOEC or BOEC and 10 µg anti-PDGF antibody ml⁻¹ (BOEC + Ab).

The anti-PDGF antibody used was a goat anti-human polyclonal IgG raised against both the A and B chains of PDGF (UBI; Upstate Biotechnology, Inc., Lake Placid, NY). Purification of the IgG fraction of goat serum was by DEAE ion-exchange chromatography. The antibody was used at a concentration of 10 µg ml⁻¹ for embryo culture studies. This was based on the suppliers report that 25 µg anti-PDGF ml⁻¹ will neutralize (100%) 10 ng PDGF-AB ml⁻¹ or 10 ng PDGF-BB ml⁻¹ and 100 µg anti-PDGF ml⁻¹ will neutralize (100%) 10 ng PDGF-AA ml⁻¹ of human, primate, porcine, bovine and murine origin based on the titrated thymidine incorporation assay using NIH-3T3 cells. The antibody exhibited no crossreactivity (< 0.1%) with IGF-I, TGF-β, acidic FGF, basic FGF or EGF when Western blot analysis and a biological neutralization assay were used.

Embryos were incubated in 96-well culture plates in serum-free MB2 medium without antibiotics in 100 µl of medium overlaid with mineral oil. All treatment groups were supplemented with 2 mg fatty-acid-free BSA ml⁻¹ to prevent rapid degradation of growth factors and their adherence to culture wells. Embryos in each treatment group (n = 85 embryos per treatment) were incubated at 39°C and 5% CO₂ in humidified air in groups of five embryos per well. Once embryos were assigned to treatment groups, the culture medium was not changed during the incubation interval and embryos remained undisturbed for the remainder of the culture period. The proportions of embryos developing beyond the 8-cell, or to the morula or blastocyst stages of development were determined 7 days following in vitro insemination.

**Embryo staining**

After the in vitro culture period, a random portion of embryos in each treatment group between > 8-cell and morula stages was stained to evaluate the number of nuclei per embryo using a DNA-specific stain, Hoechst 33342 (Purse et al., 1985). When blastocysts were formed during the treatment culture period, a double-dye technique for differential cell counts of inner cell mass and trophectoderm nuclei was performed as reported by Iwasaki et al. (1990). Initially, the

zona pellucida was removed from blastocysts with acid Tyrode’s solution and embryos were subsequently washed in TCM-199 with 10% FBS. Zona-free blastocysts were incubated with mouse anti-bovine antiserum (1:5 dilution) at 39°C (5% CO₂ in humidified air) for 30 min. After several washes in TCM-199 with 10% FBS, blastocysts were incubated (39°C and 5% CO₂ in humidified air) with guinea-pig complement serum (Sigma; 1:10 dilution), 10 μg propidium iodide ml⁻¹ (Sigma) and 10 μg Hoechst 33342 ml⁻¹ (Sigma) for 30 min. Embryos were subsequently washed in TCM-199 with 10% FBS and mounted on a glass slide for evaluation.

Statistical analysis

For embryo culture data, a randomized complete block design was used with an experimental unit consisting of five embryos incubated within 100 μl medium per well. One experimental block consisted of a group of oocytes matured, fertilized and the resulting 8-cell embryos were incubated together. The proportions of embryos in each experimental unit that developed to a specific stage divided by the total number of embryos in each unit were analysed using analysis of variance and Tukey’s test to determine significance among treatment means (Steel and Torrie, 1980).

Results comparing the mean number of nuclei per embryo were evaluated using one-way analysis of variance and Tukey’s test to separate treatment means. In addition, the total number of cells and the number of inner cell mass cells, and the proportion of inner cell mass to total cell number was evaluated using analysis of variance and means separated by Tukey’s test.

Results

Co-culture with BOEC resulted in the highest proportion of embryos developing beyond the fourth cell cycle (>8-cell). However, these results were not different (P > 0.05) from those observed for PDGF-treated embryos (Table 1). A higher (P < 0.05) proportion of embryos developed to >8-cells following incubation with PDGF or BOEC than in the MB2 or PDGF + Ab treatment groups. However, there was no difference between the proportion of embryos developing to this stage after culture with BOEC + Ab or PDGF.

A similar developmental pattern was noted for those embryos that developed to at least the morula stage 7 days following in vitro insemination (Table 1). The proportion of embryos developing to the morula stage was higher (P < 0.05) following culture with PDGF, BOEC or BOEC + Ab than those in MB2 and PDGF + Ab culture groups. Incubation of PDGF- and BOEC-treated embryos with anti-PDGF inhibited development to the morula and blastocyst stages. Although incubation of embryos with BOEC and anti-PDGF reduced embryo development to the blastocyst stage, it did not completely inhibit blastocyst development. No embryos reached
the blastocyst stage on day 7 following insemination with MB2 or PDGF + Ab, which was lower (P < 0.05) than for embryos incubated in BOEC or BOEC + Ab treatment groups. In addition, more (P < 0.05) blastocysts were formed following incubation with BOEC and BOEC + Ab compared with PDGF-treated embryos. However, incubation of embryos with BOEC resulted in a higher (P < 0.05) proportion reaching the blastocyst stage, than in all other treatment groups.

The mean number of nuclei per embryo was evaluated for those embryos between > 8-cell and morulae stages of development (Fig. 1). Incubation of embryos with BOEC or BOEC + Ab increased the number of nuclei per embryo (P < 0.05). The mean number of nuclei per embryo for BOEC (65.1) and BOEC + Ab (61.2) was higher (P < 0.05) than those for embryos incubated in MB2, PDGF or PDGF + Ab (30.8, 45.2 and 33.0, respectively). The number of nuclei per embryo was similar (P > 0.05) for embryos incubated in MB2, PDGF or PDGF + Ab.

Those embryos incubated in BOEC + Ab appeared to have a small inner cell mass, or the inner cell mass was not clearly distinguishable. In contrast, embryos incubated with BOEC alone had a distinct uniform inner cell mass (Fig. 2). The differential staining procedure indicated that the total number of cells per blastocyst was not significantly different (P > 0.05) between BOEC and BOEC + Ab treatment groups (Table 2). However, the number of inner cell mass cells was reduced (P < 0.05) in the BOEC + Ab group. In addition, the ratio of inner cell mass to total cell number was higher (P < 0.05) in the BOEC group than in embryos incubated in the presence of BOEC and anti-PDGF (19.6 versus 12.0%). Two embryos in the PDGF group formed blastocysts, but only the total number of cells (69.2) could be determined owing to their poor morphology. An example of a bovine embryo cultured in the BOEC group stained with the double-dye technique is shown (Fig. 3).

Discussion

This study demonstrated that PDGF stimulated embryo development beyond the 8-cell stage. In addition, development to the morula stage was similar for embryos incubated with PDGF and with oviductal cells. However, those embryos incubated with oviductal cells developed further (blastocyst stage) during the culture period than did PDGF-treated embryos. This study is the first to demonstrate that removal of PDGF effects with antibodies inhibits embryonic development. After neutralization of PDGF-treated embryos with antibodies (PDGF + Ab), embryonic development was similar to that of control embryos. The addition of anti-PDGF to oviductal cells (BOEC + Ab) also resulted in a 40% reduction of blastocyst formation compared with BOEC-treated embryos. The continued development of some embryos (17%) in the BOEC + Ab group may indicate that a short-term inhibition of PDGF action is overcome by continued secretion of PDGF by oviductal cells providing a developmental stimulus for further cell division. Alternatively, or additionally, the secretion of other growth factors by the oviductal epithelium may override the initial inhibitory effects imposed on embryo development by anti-PDGF. However, the addition of anti-PDGF antibody to oviductal cells at a concentration of 1 mg ml⁻¹ did not completely inhibit blastocyst formation (data not shown) suggesting the secretion of other stimulatory factors by oviductal cells.

Incubation of embryos with oviductal cells and anti-PDGF antibodies resulted in a reduced number of inner cell mass cells. In addition, the ratio of inner cell mass to total cells was lower in the BOEC + Ab group than in embryos in the BOEC group. It is not clear whether inhibition of the PDGF effect with antibodies delays differentiation of embryonic blastomeres into
inner cell mass cells or whether the rate of mitosis of inner cell mass cells is adversely affected. Another possibility is that anti-PDGF antibodies affect the integrity of the inner cell mass cells resulting in an indistinct inner cell mass, thereby allowing complement-mediated lysis during immunosurgery and staining with propidium iodide.

Larson et al. (1992) suggested that the ability of PDGF to signal activation of the embryonic genome is independent of TGF-β and bFGF action, but TGF-α and bFGF may act synergistically to promote blastulation in PDGF-treated embryos. Results of our study also indicate that PDGF alone can stimulate embryonic development to the morula stage. Larson et al. (1992) also suggested that, following its acceleration of the fourth cell cycle, PDGF inhibits embryo blastulation. However, results from our study suggest that the apparent inhibition of blastocyst formation by PDGF is probably due to poor embryonic survival rates or suboptimal culture conditions, i.e., more PDGF-treated embryos degenerated during culture owing to the absence of additional development stimuli (possibly from TGF-α, TGF-β or bFGF) required at the fifth cell cycle.

Watson et al. (1992) demonstrated that PDGF-A, TGF-α and TGF-β2 genes were expressed in bovine embryos as both maternal and embryonic transcripts. In addition, the PDGF-α receptor gene was a product of maternal and embryonic origin in bovine embryos. Munson et al. (1992) reported that TGF-β and PDGF act synergistically to promote proliferation of bovine trophoblastic cells and endometrial cells during in vitro culture. A greater mitogenic response resulted from combining TGF-β and PDGF-AB compared with TGF-β and PDGF-BB. Marquand-Le Guen et al. (1989) noted that TGF-β stimulated mitotic activity of inner cell mass cells of bovine embryos that may have been mediated via its actions on the somatic cells during co-culture. Previously, Wood and Kaye (1989) failed to demonstrate a stimulatory effect of EGF on mouse embryo development. However, EGF stimulated uptake of [3H]leucine in late morulae and blastocyst stage embryos, and the increased protein synthesis was specific to trophectodermal cells. It was concluded that EGF stimulation was specific to trophectodermal cells and that EGF expression may occur at the late morula stage. These results are further supported by a report that specific binding of EGF is restricted to trophoblast outgrowths during in vitro culture (Adamson and Meek, 1984).

The reduction of inner cell mass cells and the proportion of inner cell mass to total cells following treatment with anti-PDGF antibodies may be related to the cellular actions of PDGF. The actions of growth factors may include effects on their mitosis or differentiation and direct influences on the embryo or its uterine environment (Rappolee et al., 1988). PDGF may elicit the synthesis of specific proteins necessary for mitosis in the inner cell mass following differentiation. In cultured 3T3 cells, PDGF stimulates the synthesis of cyclin (Bravo and Macdonald-Bravo, 1984). In addition, the expression of c-myc or c-fos may have been limiting following treatment with anti-PDGF antibodies. Larson (1991) noted that the expression of c-myc and c-fos was detected in PDGF-treated embryos but not in developmentally arrested embryos. Similarities exist between the absence of c-myc and c-fos expression in cell lines arrested in the G0 state (Baserga, 1983; Pardee, 1989) and developmentally arrested bovine embryos (Larson, 1991). These proto-oncogenes, activated prior to the period of cell differentiation of trophectoderm and inner cell mass, may

BOEC: bovine oviductal epithelial cells; BOEC + Ab: bovine oviductal epithelial cells plus platelet-derived growth factor antibody.

Fig. 3. A bovine embryo co-cultured with oviductal cells until 7 days following in vitro fertilization and differentially stained with propidium iodide and Hoechst stain to distinguish the inner cell mass. The inner cell mass was positioned dorsal to the trophoderm prior to fixation on the slide (× 240).
regulate formation of the inner cell mass. It is unclear whether PDGF initiates activation of the embryonic genome or drives embryo development after genome activation. However, it is plausible to assume that PDGF drives embryo development after activation, since the developmental 'block' in cultured bovine embryos is not due to failure of the embryonic genome to initiate transcription (Barnes and First, 1991).

This study strongly suggests that at least a part of the beneficial effect of co-culture of bovine embryos with oviductal epithelium is due to platelet-derived growth factor. The roles of other growth factors in regulating embryo differentiation have yet to be fully determined. However, the oviductal epithelium may serve as a source of these growth factors. Determining the mechanisms of growth factor regulation of inner cell mass formation may provide an efficient method for studying embryonic differentiation in vitro.

The authors are grateful to J. F. Dickey (Clemson University) and his staff for supplying the ovarian tissue. J. R. Giles (Cornell University) for the antibody used for immunosurgery and Y. Menezo (INSAA) and API Biomerieux (France) for providing the MB2 medium. Appreciation is also extended to J. R. Broussard and L. Zhang for laboratory assistance. The authors thank Louisiana Animal Breeders Cooperative for providing the semen used in the study. This manuscript was approved for publication by the Director of the Louisiana Agricultural Experiment Station as manuscript number 92-11-6173.
