Effects of tamoxifen on the fertility of male rats

Institute for Research in Reproduction (ICMR), Parel, Bombay 400 012, India

The effects of oral administration of tamoxifen (a synthetic non-steroidal anti-oestrogen) at doses of 40, 200 or 400 µg kg⁻¹ day⁻¹ on the circulating concentrations of LH, FSH, prolactin, testosterone and oestradiol, weights of pituitary, testes, secondary sex organs and the fertility of adult male rats were determined. The drug was administered per os daily, for up to 90 days. The fertility of rats treated with tamoxifen for 60, 70, 80 or 90 days was assessed by allowing them to mate with normal female rats of proven fertility. Tamoxifen at 40 µg kg⁻¹ day⁻¹ reduced concentrations of testosterone in plasma but had no affect on LH, FSH, prolactin and oestradiol concentrations, and the weights of pituitary, testes, epididymides, ventral prostate and seminal vesicles. Tamoxifen at 40 µg kg⁻¹ day⁻¹ reduced potency, fecundity, the number of implantation sites, the fertility index and litter size. Tamoxifen at 200 and 400 µg kg⁻¹ day⁻¹ reduced the concentrations of LH and testosterone in plasma and the weights of testes and secondary sex organs compared with controls. Tamoxifen at 400 µg kg⁻¹ day⁻¹ was most effective in reducing the number of viable pups, the litter size (≤ 1) and the fecundity (20%). The potency of treated rats (a measure of the presence of an ejaculate) was significantly decreased when compared with controls, but copulation was apparently not affected as mated female rats showed a constant dioestrous phase. Histology of the testes revealed disorganization of the cytoarchitecture of the tubules with obliterated lumen. All the parameters affected by tamoxifen at 200 µg kg⁻¹ day⁻¹ returned to normal values when tamoxifen was withdrawn for 90 days.

Introduction

The biological effects of tamoxifen, a synthetic non-steroidal anti-oestrogen, are complex and range from complete oestrogen antagonism to pure oestrogen agonism depending upon its concentration, the sex of the animal and the target organ. In humans and rats, tamoxifen is predominantly anti-oestrogenic with residual oestrogenic activity (Furr and Jordan, 1984).

The hypothalamus plays a crucial role in the maintenance of spermatogenesis by controlling the secretion of LH and FSH from the pituitary via GnRH (Schally et al., 1972). Testosterone and oestradiol are involved in the feedback regulation of GnRH synthesis and release via a long-loop feedback mechanism (Kalra and Kalra, 1983). Receptors for oestradiol are present in the hypothalamus (McEwen, 1975; Kato, 1977), pituitary (Muldoon, 1977), epididymides (Kamal et al., 1985; Tekpetey and Amann, 1988), Leydig cells and Sertoli cells (Van Beurden-Lamers et al., 1974; Nakhta et al., 1984). Oestradiol receptors in the Leydig and Sertoli cells presumably play an important role in the paracrine regulation of spermatogenesis (Skinner, 1991). The hypothalamus, pituitary, epididymis and the Sertoli and Leydig cells are important components of the male reproductive system. The contention that tamoxifen with its intrinsic oestrogen antagonist–agonist activities may interfere with male fertility is reasonable. In fact, tamoxifen is anti-gonadotrophic in male rats (Harper and Walpole, 1967). Daily administration of tamoxifen to male rats for 3–6 months reduces the weights of testes, accessory sex glands and arrests spermatogenesis (Furr et al., 1979; Wantanabe et al., 1980). Tamoxifen reduces testosterone production by Leydig cells in vitro (Lin et al., 1981); concentrations of LH and testosterone in plasma are significantly reduced following treatment with tamoxifen (Barlke et al., 1978), and plasma concentrations of LH and testosterone are increased in oligozoospermic patients responding to tamoxifen therapy (Willis et al., 1977; Vermeulin and Comhaire, 1978; Noci et al., 1985; Ain Melk et al., 1987). Despite the fact that tamoxifen has been available for two decades and its biochemical, pharmacological and toxicological effects have been documented, no systematic attempt has been made to evaluate the effect of tamoxifen on male fertility as with clomiphene citrate, a non-steroidal anti-oestrogen structurally related to tamoxifen (Nelson and Patanelli, 1962; Roy et al., 1964; Kalra and Prasad, 1967; Heller and Heller, 1970; Flickinger, 1977). The study reported here describes the temporal effect of different doses of tamoxifen on plasma hormonal profiles, tissue weights and reproductive performances of male rats.

Materials and Methods

Animals

Randomly bred male and female Holtzman strain rats were maintained at a temperature of 22–23°C, humidity 50–55%, and lighting cycle of 14 h light:10 h dark. Commercial rat pellets and water were available ad libitum. Seventy-five-day-old male rats and ninety-day-old female rats of proven fertility were used.

Tamoxifen

Tamoxifen citrate tablets containing 10 mg of tamoxifen were obtained from Lyka (Bombay). The drug was suspended uniformly in water by sonication and administered daily, per os, between 10:00 and 12:00 h via a rat feeding tube.

Mating studies

The mating design was either 1 male × 1 female or 1 male × 3 females. Female rats were housed with treated or control male rats on the evening of pro-oestrus. As it was difficult to obtain a large number of female rats at pro-oestrus in a single batch, the male rats were exposed to pro-oestrous females within ±1 day of the treatment schedule. The occurrence of mating was confirmed by the presence of a copulatory plug or spermatozoa in the vaginal smear on the following morning.

Experimental protocol

The study was designed to evaluate the reproductive performance of male rats treated with three different doses of tamoxifen. The male rats were assigned to four groups of ten rats each and received either saline or 40, 200 and 400 μg tamoxifen kg⁻¹ day⁻¹, respectively. Each group of rats was allowed to mate with female rats (1 male × 3 females) after 60, 70, 80 and 90 days of tamoxifen administration. Inseminated rats were caged individually and observed during the ensuing pregnancy. Normal delivery occurred between day 21 and day 22 of pregnancy. Litter size and the viability of the pups were recorded. The rats were killed within a few hours after delivery or on day 23 of pregnancy, if they failed to produce young. Ovaries were examined for corpora lutea, and uterine horns were examined for number of implantation sites and resorbed fetuses. Female rats that failed to show a vaginal plug or spermatozoa in the vaginal smears were monitored for oestrous cyclicity for a further 10 days. Rats that showed continuous dioestrous for at least 1 week were considered pseudopregnant. The following parameters were determined.

Potency. The ability of male rats to inseminate females was expressed as the ratio of female rats inseminated to the number of female rats exposed for mating × 100.

Fertility index. The index of the ability of spermatozoa to fertilize ova was expressed as the ratio of the number of implantation sites to the number of corpora lutea (per two ovaries).

Percentage fecundity. The measure of the ability of male rats to sire viable pups was expressed as the ratio of the number of males siring at least one viable pup to the total number of males exposed for mating × 100. The loss in fecundity indicated complete loss in the ability of spermatozoa to fertilize ova.

Autopsy of animals. The control and treated male rats were killed by decapitation. Blood from the trunk was allowed to clot at 4°C overnight. Serum was collected by centrifugation at 800 g for 20 min and stored frozen at −300°C for radioimmunoassay of LH, FSH, prolactin, testosterone and oestriol. Testes, pituitary gland and accessory sex organs were collected from each rat. The organs were weighed on a torsion balance. Plasma was stored at 30°C for radioimmunoassay of LH, FSH, prolactin, testosterone and oestriol.

Histology of tissues. Testicular tissues were fixed in modified Karnovsky’s fixative as modified by David et al. (1973), washed in 0.1 mol cacodylate buffer 1−1, post-fixed in 1% osmium tetroxide, dehydrated in an ascending series of acetone (30–100%), embedded in Araldite and semi-thin sections were cut at 0.5 μm intervals. The sections were stained with toluidine blue (E. Merck, Darmstadt) and observed under bright-field optics at ×40 or ×100. Sodium cacodylate, osmium tetroxide and Araldite were from Pelco International (Redding, CA).

Hormone assays. LH, FSH and prolactin were assayed as described by Balasiner et al. (1992). The standard curve for LH (NIADDK-Rat-LH-RP-2) ranged from 10 pg to 12.5 ng per assay tube, and for FSH (NIADDK-Rat-FSH-RP-2) from 10 pg to 12.5 ng per assay tube. The inter- and intra-assay coefficients of variations were 9 and 6% for LH, and 10% and 6% for FSH assays, respectively. The standard curve for prolactin (NIADDK-Rat-PRL-RP-3) ranged from 10 pg to 25 ng per assay tube. Interassay and intra-assay coefficients of variations for prolactin were 14 and 5%, respectively. Testosterone and oestriol were assayed as described by Juneja et al. (1991). The standard curves ranged from 3.9 to 500 pg for testosterone, and from 5 to 200 pg for oestriol. Intra- and interassay coefficients of variation were 5.5 and 11% for testosterone, and 6 and 10% for oestriol, respectively.

Statistical analysis

Hormone concentrations and tissue weights were subjected to analysis of variance. Significant difference between groups was determined using Duncan’s multiple range test. The level of significance was set at P ≤ 0.05. Data relating to implantation sites, potency and fertility index were subjected to non-parametric Kruskal–Wallis one-way ANOVA.

Results

Effect of tamoxifen on implantation sites, fertility index and litter size

40 μg tamoxifen kg⁻¹ day⁻¹. The total number of implantation sites in female rats (F) mated with males treated with tamoxifen for 60, 70, 80 and 90 days (F(60), F(70), F(80) and F(90)) was significantly lower than that of controls, F(C) (Table 1).
The mean rank value of 62.96 for implantation sites in F(C) decreased significantly to 34.0, 37.5, 26.3 and 39.11 in F(60), F(70), F(80) and F(90), respectively. The number of implantation sites per uterus ranged from 11 to 15 in controls, and between 0 and 14 in the females mated with males fed tamoxifen for 60, 70, 80 or 90 days.

The fertility index was 0.97 for F(C) and ranged from 0.73 to 1 in controls, and between 0 and 1 in F(60), F(70), F(80) and F(90). The fertility index was significantly lower as indicated by a significant fall in mean rank value of fertility index in F(C) from 61.46 to 32.57, 32.50, 28.27 and 42.11 in the F(60), F(70), F(80) and F(90) groups, respectively.

The size of the litter delivered by F(C) was 11 and was significantly reduced in F(60), F(70), F(80) and F(90). The litter size for F(C) ranged between 7 and 14, whereas for treated groups it ranged from 0 to 14. The minimum number of viable pups delivered by F(C) was seven, whereas it was three, seven, one and six for F(60), F(70), F(80) and F(90), respectively.

200 μg tamoxifen kg⁻¹ day⁻¹. The total number of implantation sites was significantly lower in F(60), F(70), F(80) and F(90) compared with that of F(C). This was evident from a significantly lower mean rank value of implantation sites in F(C) 46.60 and 31.38, 27.15, 16.25 and 22.70 in F(60), F(70), F(80) and F(90), respectively. The number of implantation sites per uterus ranged between 10 and 14 in F(C), and between 0 and 14 in F(60), F(70), F(80) or F(90).

The fertility index was 1.0 for F(C). It ranged from 0.14 to 1, 0.15 to 1, 0 to 0.8 and 0 to 1 in F(60), F(70), F(80) and F(90), respectively. The fertility index was significantly lower in females mated with tamoxifen-treated males as shown by the significantly lower mean rank values of fertility index of these groups compared with controls.

The size of the litter delivered by F(C) was ten. It ranged from 6 to 14, 0 to 13, 0 to 14, 0 to 4 and 0 to 12 in F(C), F(60), F(70), F(80) and F(90), respectively. The litter size was significantly smaller in female rats mated with tamoxifen-treated male rats as shown by a significantly lower mean rank value of litter size in treated groups compared with controls. The minimum number of pups delivered by F(C) was six, whereas it was three, four and one for F(60), F(70), F(80) and F(90), respectively.

400 μg tamoxifen kg⁻¹ day⁻¹. There were fewer implantation sites in the groups of females mated with treated male rats compared with controls. The number of implantation sites was zero in F(70) but was three, seven and ten in F(60), F(80) and F(90), respectively. The number of implantation sites per uterus ranged from 0 to 3 in F(60), and 0 to 7 and 0 to 9 in F(80) and F(90), respectively.

The fertility index was close to zero in the treated groups. Treatment with tamoxifen resulted in significantly fewer pups delivered by F(60), F(70), F(80) and F(90) compared with controls. No viable pups were delivered by F(70). The litter size was zero or one in the treated group. The minimum number of viable pups delivered by F(60), F(80) and F(90) was three, seven and one, respectively.

### Effect of tamoxifen on the potency and fecundity of rats

The potency and fecundity of male rats treated with tamoxifen was significantly lower than that of controls (Table 2). Tamoxifen at 400 μg kg⁻¹ day⁻¹ was more effective than at 40 μg kg⁻¹ day⁻¹ in suppressing potency and fecundity of rats.

### Effect of tamoxifen on tissue weights

Tamoxifen did not affect the weights of testes, seminal vesicles, epididymides, ventral prostate glands and the pituitary glands at 40 μg kg⁻¹ day⁻¹ for 90 days (Table 3). At 200 and 400 μg kg⁻¹ day⁻¹ the weights of ventral prostate glands, seminal vesicles and epididymides were significantly lower than controls.

**Effect of tamoxifen on plasma hormone concentrations**

Tamoxifen, at all doses tested, reduced testosterone concentrations significantly compared with saline treated controls (Table 4). FSH, prolactin and oestradiol concentrations were unaffected. Plasma LH was significantly lower after treatment with 200 and 400 µg tamoxifen kg\(^{-1}\) day\(^{-1}\) than in controls. Tamoxifen at 40 µg kg\(^{-1}\) day\(^{-1}\) did not affect concentrations of LH in plasma. There were no significant changes in the serum profiles of FSH, prolactin and oestradiol following tamoxifen treatment.

**Effect of tamoxifen on testicular histology**

The cytoarchitecture of the seminiferous tubules was disorganized in treated rats (Fig. 1). In the treated groups fewer tubules contained a lumen and the lumen of some tubules was filled with cellular debris. The disorganization of germ cells increased the intercellular space and there was loose intercellular contact within the germinal epithelium. This was predominantly seen in the basal compartment of the epithelium. Cells lying on the basement membrane, that is Sertoli cells, spermatagonia and preleptotene spermatocytes frequently appeared to be isolated from the neighbouring cells. The disorganization of the germinal epithelium after tamoxifen treatment was also shown by the occurrence of spermatocytes and predominantly premature spermatids in the tubular lumen. There was no significant change in tubular diameter. Leydig cells were well preserved and appeared normal.

**Reversibility of tamoxifen-induced effects**

Reversibility studies were performed with 200 µg tamoxifen kg\(^{-1}\) day\(^{-1}\). All the parameters affected by tamoxifen, weights of seminal vesicles, ventral prostate glands, epididymides, concentrations of LH and testosterone in plasma, potency, fecundity, fertility index and litter size were corrected after 90 days of drug withdrawal (Table 5).

**Discussion**

Tamoxifen is used extensively in the treatment of breast cancer and has been in clinical use for over two decades (Jordan

and Murphy, 1990). It has few side effects, and has also been recommended for prophylactic treatment of women prone to breast cancer (Buckley and Goa, 1989). Tamoxifen has also been recommended for the treatment of oligozoosperma (Willis et al., 1977; Vermeulin and Comhaire, 1978; Noci et al., 1985; Ain-Melk et al., 1987), and gynaecomastia (Patterson et al., 1980; Parker et al., 1986), at doses ranging from 10 to 30 mg day⁻¹.

In the study reported here, tamoxifen administered at 40 μg kg⁻¹ day⁻¹ for 90 days did not affect the weights of testes, accessory sex organs and the pituitary. It affected a reduction in the number of implantation sites, fertility index, litter size, fertility and potency. Testosterone concentrations in plasma were lower than in controls, but there were no changes in concentrations of LH, FSH, prolactin and oestradiol. These results suggest that tamoxifen has a direct effect at the testicular level, probably on Leydig cells and inhibits testosterone production. This contention is supported by earlier observations that tamoxifen reduced testosterone production by Leydig cells in vitro (Lin et al., 1981). As the sperm fertilizing potential depends on circulating testosterone (Orgebin-Crist et al., 1975), a lower concentration of circulating testosterone may have affected the sperm fertilizing potential.

Tamoxifen at 200 μg kg⁻¹ day⁻¹ reduced the weights of seminal vesicles, ventral prostate glands and epididymides. It also caused a significant reduction in concentrations of LH and testosterone, without affecting concentrations of FSH, prolactin and oestradiol. If the effects of tamoxifen were limited to testicular tissue causing ‘chemical castration’, lower testosterone concentrations would have activated regulatory ‘long-loop’ feedback mechanisms to increase the secretion of LH. Our finding of a decrease, rather than an increase, in circulating LH suggests that 200 μg tamoxifen acted as an ‘oestrogen’ agonist at the hypotalamus–pituitary axis by inhibiting the secretion of LH by the pituitary. The reduction in LH may have accentuated the reduction in weights of accessory sex organs by further decreasing circulating concentrations of testosterone by reducing synthesis of testosterone by Leydig cells. The possibility that weights of accessory sex glands were low owing to oestrogen ‘agonist’ activity of tamoxifen cannot be ruled out, as oestradiol is known to affect the weights of accessory sex organs by direct action (Robaire et al., 1979). Tamoxifen at 200 μg also reduced the number of implantation sites, fertility index, litter size, fertility and potency.

Although plasma testosterone, fertility index and litter size of rats treated with 40 or 200 μg tamoxifen for 90 days did not differ significantly from each other, they were significantly less and more comparable with controls or with rats treated with 400 μg tamoxifen, respectively. The data indicate that reduction in fertility index and litter size paralleled the lower concentrations of testosterone. A pronounced reduction in concentrations of testosterone in plasma in rats administered 400 μg tamoxifen was accompanied by a pronounced reduction in fertility index and litter size compared with that of controls or groups receiving 40 or 200 μg tamoxifen kg⁻¹ day⁻¹. It is inferred that sperm fertilization potential is sensitive to concentrations of testosterone in plasma and is impaired on its reduction. The sperm fertilization potential is virtually zero in the presence of low circulating testosterone.
Tamoxifen at 400 μg kg⁻¹ day⁻¹ reduced the fertility index to nearly zero and adversely affected the insemination capacity of male rats. Tamoxifen at this dose induced almost complete sterility in treated rats and there was a marked reduction in the number of viable pups sired by a male.

The potency of male rats treated with 400 μg tamoxifen for 60, 70, 80 or 90 days was adversely affected. It was not clear whether loss in potency was concomitant with loss in libido. Most of F(60), F(70), F(80) and F(90) failed to show a vaginal plug or presence of spermatozoa in vaginal smears. The vaginal smears on subsequent days showed that these females were at persistent dioestrous, thereby indicating that mating had occurred. Thus, it could be concluded that tamoxifen at 400 μg impaired fertility of male rats without completely abating mating behaviour. Concentrations of testosterone and LH were markedly reduced as were the weights of testes, seminal vesicles, ventral prostate glands and epididymides. Pituitary weights were not affected. Testosterone deprivation is known to affect potency of rats (Orgebin-Crist et al., 1975). The ability to mate may have been maintained owing to oestriadiol concentrations (Sodersten, 1979) or owing to low plasma testosterone which was sufficient for normal mating behaviour but not for maintenance of fertility potential of spermatozoa (Bhasin et al., 1988).

Tamoxifen-treated male rats, irrespective of dose of the drug administered, showed variations in individual fecundity. Some of the rats that were completely sterile on days 60 and 70 of tamoxifen treatment were fertile when tested on days 80 or 90 of drug administration. This may be attributable to extensive metabolism of tamoxifen to several active metabolites with different biological activities (Patterson et al., 1980). In fact, several investigators have demonstrated that women with breast cancer who are receiving tamoxifen therapy have very low steady-state concentrations of 4-hydroxytamoxifen in plasma, while N-desmethyl tamoxifen concentrations are about 50% higher than those of tamoxifen itself. According to Patterson et al. (1980), concentrations of tamoxifen in plasma were maximal 3 h after oral administration and steady state concentrations of tamoxifen and N-desmethyl tamoxifen in plasma of healthy male volunteers were achieved at 4 and 7 days, respectively. Bowman et al. (1982) observed that the serum concentrations of tamoxifen and 4-hydroxytamoxifen in ovariectomized rats measured after a single dose of tamoxifen (7 mg kg⁻¹) were maximal after 24 h and were undetectable by 4 days, at which time the nuclear and cytosol oestrogen receptor contents remained altered and were not restored to original values. According to Bowman et al. (1982), changes in oestrogen receptors after administration of tamoxifen may not only be simply related to the serum concentrations of tamoxifen and its metabolites, but also to the retention of ligand within the target tissue. Attempts are being made in our laboratory to measure tamoxifen and its metabolites in male rats treated with tamoxifen for varying periods.

Histological examination of treated testes showed marked disorganization of the cytoarchitecture of the tubule and obliteration of the lumen. The normal arrangement of germ cells and Sertoli cells was difficult to identify. Organization of the germ cells and cell associations which represent the stages of the seminiferous cycle could not therefore be correctly assessed. Microtubules of Sertoli cells play an important role in the main-tenance of the normal cytoskeleton of rat testis seminiferous epithelium and spermatogenesis (Allard et al., 1993). It is possible that the observed disorganization of the cytoarchitecture of the seminiferous tubule and impaired spermatogenesis may have been due to disturbed functioning of Sertoli cells. If this postulate is accepted, then why, how and what functions of Sertoli cells were actually altered remain to be elucidated. The changes induced by tamoxifen were completely reversed on drug withdrawal, which resulted in normalization of accessory sex organ weights, circulating concentrations of LH and testosterone, potency and fecundity of tamoxifen treated rats.

In summary, evidence is presented that tamoxifen at a particular dose range (40–400 μg kg⁻¹ day⁻¹) affects the potency and fecundity of male rats reversibly, most probably without changes in mating behaviour. An effective hormonal contraceptive regime for men has not yet been developed despite much work. A major impediment in the process has been the risk of a decrease or loss of libido owing to hormonal interception. The study reported here suggests that the potential of using tamoxifen for male contraception should be explored further.

Special reagents for radioimmunoassays were provided by the National Institutes of Health, Bethesda under Indo-US Agreement (No. 01-05I) on Science and Technology. The authors acknowledge the valuable help of D. Balaiah, Senior Research Officer (Statistics) in statistical analyses of the data. The technical assistance of H. G. Pawar is acknowledged and S. V. Nair is thanked for typing this manuscript.
